among alcoholics. The samples used in the study consisted of alcoholics in two stages of recovery and a sample of non-alcoholic controls. The California Psychological Inventory (CPI; Gough, 1957) and a biographical data sheet were administered to all subjects, and multivariate data analysis techniques were used to determine differential personality patterns for the three samples. Since the research was intended to identify factors related to positive adjustment as well as clinical symptomatology, the CPI appeared to be a logical choice as an assessment device. The CPI is designed for use with a general population and yields information on the adequacy of interpersonal as well as intrapersonal functioning.

Method

Subjects

Three samples (total $N = 183$) were used in this study. Group 1, the short-term recovered alcoholics, consisted of 60 "dry" alcoholics with at least 3 weeks but less than 4 months of sobriety (30 males and 30 females). The majority were residents in halfway houses in the Miami, Florida, area, and 19 were new members from Alcoholics Anonymous (AA). Group 2, the long-term recovered alcoholics consisted of 62 sober alcoholics (31 males and 31 females) with a *minimum* of 4 years of continuous sobriety, the mean length of sobriety being 8.9 years. All participants in Group 2 were active members of AA. Group 3, the nonalcoholic controls, consisted of 61 adult subjects (30 males and 31 females) chosen at random from the Miami, Florida, area. All members of the control group reported moderate to infrequent or no use of alcohol.

All subjects were between the ages of 30 and 65. From the information available, the sober alcoholic and the nonalcoholic control groups appeared to be matched in terms of socioeconomic status. The dry alcoholics, on the other hand, ranked somewhat lower in terms of the traditional indices of socioeconomic status (e.g., occupation, income, etc.). These differences, however, appear to be related to the duration of their alcoholism and the recency of their recovery more than their actual status. The mean ages of the groups were as follows: dry alcoholics, 46 years ($SD = 8.1$); sober alcoholics, 49 years ($SD = 11.1$); nonalcoholic controls, 49 years ($SD = 8.4$).

Procedure

The CPI and a biographical data sheet were administered to all participants individually or in small groups. For the sober alcoholics, most of the ad-

ministration was conducted at informal meetings of active members of AA in the Miami area. The CPI was administered to the dry alcoholics, with the exception of the 19 new members of AA, on site at the various halfway houses in the Miami area. For the nonalcoholic controls, the CPI was administered in small groups to adult volunteers drawn from a wide variety of occupations (firefighter, meat cutter, pilot, postal worker, teacher, homemaker, etc.) and social backgrounds. The CPI was scored for the 18 standard scales plus an additional scale developed by Hogan (1969).

Results

A 2×3 multivariate analysis of variance (Clyde, 1969), using raw scores on the CPI scales as dependent variables, was conducted to determine the existence of sex and group differences on the CPI profiles. A multivariate test of significance, using Wilk's lambda

criterion, indicated a significant main effect due to sex, $F(19, 159) = 9.64, p < .001$, but no significant Sex \times Group interaction, $F(38, 318) = .899, p > .05$. An examination of the univariate F tests for the main effect of sex further indicated that males scored significantly higher on Well-Being (Wb), $F(1, 177) = 4.64, p < .05$; and females scored higher on Achievement via Independence (Ai), $F(1, 177) = 5.30, p < .01$, and Femininity (Fe), $F(1, 177) = 149.36, p < .001$.

The multivariate analysis of variance also yielded a significant main effect for group, $F(38, 318) = 3.37, p < .001$. More importantly, the pattern and direction of the significant differences obtained for the univariate F tests conducted for the individual scales provided strong evidence for the existence of

distinctive personality profiles for each of the groups. Fifteen of the 19 univariate F tests were significant at the .001 level, and 31 of the 57 post hoc comparisons were significant at more than the .05 level. Table 1 presents the means, standard deviations, and F ratios for all of the CPI scales for the three samples. Table 1 also presents the post hoc comparisons between means using Scheffé's S method (Kirk, 1968).

The single most notable finding reported in Table 1 is the large number of significant differences between the personality profiles of all three groups. As can be seen from Table 1, the personality profiles of alcoholics in two stages of recovery (i.e., newly recovered and long-term recovered) differed significantly from nonalcoholic controls and from each other. The results of the group comparisons can be summarized as follows: First, the profile of the sober alcoholics differed significantly from that of the nonalcoholic controls on the following nine scales: Capacity for Status (Cs; $p < .01$), Sociability (Sy; $p < .01$), Responsibility (Re; $p < .05$), Socialization (So; $p < .001$), Self-control ($p < .05$), Good Impression ($p < .01$), Achievement via Conformance (Ac; $p < .01$), Intellectual Efficiency ($p < .05$), and Empathy (Em; $p < .05$). Moreover, the nonalcoholic controls exhibited a more normal profile, scoring higher than the sober alcoholics on all nine scales. Second, the dry alcoholics had an *extremely* depressed profile in comparison to that of the nonalcoholic controls. The dry alcoholics scored significantly lower on all but the following four scales: Social Presence, Communality, Flexibility, and Fe. Furthermore, 13 of the 15 significant differences were in excess of .001. Finally, in comparison to the dry alcoholics, the sober alcoholics in general exhibited a more elevated profile, scoring higher than the dry alcoholics on the following seven scales: Wb ($p < .05$), Re ($p < .001$), So ($p < .05$), Tolerance ($p < .05$), Ac ($p < .05$), Ai ($p < .01$), and Psychological-mindedness ($p < .05$).

The second phase of the analyses was designed to determine the personality dimensions most useful in differentiating among the groups. A multiple discriminant analysis was conducted using group membership as a

Figure 1. Group centroids for discriminant functions I and II.

criterion variable and CPI scale scores as predictor variables (Cooley & Lohnes, 1971). The analysis yielded two significant discriminant functions; and a measure of overall group differentiation, Wilk's lambda, indicated that both functions significantly discriminated between groups ($p < .001$). The centroids of the three groups are plotted in Figure 1, with the first significant discriminant function serving as the ordinate and the second discriminant function serving as the abscissa. These group centroids are the mean scores for the individuals within each group for the two significant functions.

The first and most important dimension for differentiating between groups, which accounted for 69.6% of the between-group variance, was a bipolar dimension defined on the positive end by So (.56), Re (.41), and Em (.37) and defined on the negative end by Sy (-.37). This dimension, which was labeled *interpersonal values*, appears to reflect a socially mature, empathic, and articulated value system versus a primarily affiliative, other-directed value orientation. From the post hoc comparisons presented in Table 1, it can be seen that the dry alcoholics had the lowest scores on So, Re, and Em (the CPI "moral" scales) and Sy (a measure of interpersonal affiliation). More importantly, as can be seen from Figure 1, the first func-

tion differentiates among all three groups, with the nonalcoholic controls scoring highest and the dry alcoholics scoring lowest.

The second significant function, which accounted for 30.4% of the between-group variance, is a dimension of general profile elevation. Nine of the CPI scales loaded above .35 on this function, whereas only four loaded above .35 on the first function. This dimension of general profile elevation is defined primarily by Self-Acceptance (Sa) (.58) and Wb (.56) on the positive end and by Sy (-1.36) on the negative end. High scores on Sa indicate the presence of a positive self-image and high self-esteem; high scores on Wb indicate a sense of well-being and a freedom from excessive health concerns. Low Sy scores, on the other hand, indicate social detachment, passivity, and generally poor interpersonal functioning. This dimension, which was labeled *interpersonal identity*, appears to reflect a relatively conflict-free and comfortable sense of personal worth versus uncertainty in self-evaluation resulting in a need for interpersonal supports. The significance of this dimension can be seen from the pattern of centroid plots displayed in Figure 1. The sober alcoholics scored highest on this function, whereas the dry alcoholics and the nonalcoholic controls obtained about the same mean centroid, suggesting that long-term recovered alcoholics display a unique psychological adjustment profile. On this dimension, long-term recovered alcoholics appeared to be relatively nonneurotic but moderately socially maladjusted. Confirmation of this interpretation can be found in Table 1. The sober alcoholics did not differ significantly from the nonalcoholic controls on Sa or Wb, but they scored significantly lower than the controls on Cs and Sy.

For the final phase of the analyses, subjects in all three groups were scored for a CPI-based "social maturity index" developed by Gough (1966). The social maturity index was originally defined by comparing the responses of a large sample of delinquents and nondelinquents on the CPI and developing a six-variable regression equation to distinguish between the groups. Subsequent research (Gough, De Vos, & Mizushima, 1968; Hogan, Mankin, Conway, & Fox, 1970) has estab-

lished the utility of the social maturity index as a measure of antisocial tendencies. The constant and the weights for the equation have been adjusted so that the mean score on the index in a normal population will be 50.0. In the original sample, the nondelinquent mean was 50.4 and the mean delinquent score was 42.7. Mean scores for the dry alcoholics, sober alcoholics, and nonalcoholic controls used in this study were, respectively, 45.4 ($SD = 3.7$), 47.2 ($SD = 3.2$), and 49.4 ($SD = 3.3$). A one-way analysis of variance, using social maturity scores as the dependent variable, was highly significant, $F(2, 180) = 22.05$, $p < .001$. Post hoc comparisons, using Scheffé's S method, were significant at or above the .05 level for all paired comparisons.

Discussion

This study presents data on the personality characteristics of alcoholics in two phases of recovery. A multivariate analysis of variance was used to determine group differences on the personality variables, and a multiple discriminant analysis was utilized to identify the most useful dimensions for differentiating between both groups of alcoholics and a group of nonalcoholic controls. The overall results of the analyses indicate the existence of differential patterns of adjustment and coping strategies at each stage of recovery.

The personality profile of the alcoholics in the initial stages of recovery showed a marked similarity to common personality patterns identified in previous research. The profile of the newly recovered alcoholics can be summarized as follows: First, the dry alcoholics exhibited an extremely depressed profile, indicating a generally poor level of adjustment. Second, this group was characterized by strong antisocial tendencies and impulsiveness, scoring significantly lower on the social maturity index than both other groups. Third, the dry alcoholics appeared to exhibit a sense of interpersonal inadequacy, low self-esteem, and feelings of guilt and self-blame. This overall pattern is notably consistent with several of the modal personality profiles reported in previous research with alcoholic patients. In particular, the CPI profile of the newly recovered alcoholics in this study bears

a strong resemblance to the Type II personality (impulsive-socially deviant) identified by Skinner et al. (1976) using the DPI, and to the Type B personality (extremely low impulse control) identified by Nerviano (1976) using the PRF and the Sixteen Personality Factor Questionnaire. The convergence of results obtained with such a wide range of assessment devices provides strong evidence for the pervasiveness of this personality type among alcoholics at this stage of recovery.

The long-term recovered alcoholics, on the other hand, displayed a unique personality profile, differing from both the newly recovered alcoholics and the nonalcoholic controls. The profile of the sober alcoholics can be described as follows: First, the sober alcoholics displayed a generally more elevated profile than the dry alcoholics but significantly less elevated than the controls, a finding which suggests that the maintenance of long-term sobriety is associated with an overall improvement in general level of adjustment. Second, the sober alcoholics appeared to be moderately undersocialized in terms of intrapersonal values. As a group, they obtained a midrange score on the social maturity index. Moreover, they scored significantly higher on Re and So than the dry alcoholics but lower than the nonalcoholic controls, suggesting that recovery is significantly but not exclusively related to a restructuring of intrapersonal values. Third, the sober alcoholics displayed a pattern of poor interpersonal functioning similar to that of the dry alcoholics. As a group, they scored significantly lower on Cs and Sy than the controls, indicating a sense of interpersonal inadequacy and social inhibition. This generally poor level of interpersonal functioning stands in sharp contrast to their generally good level of intrapersonal functioning. They did not differ significantly from the controls on CPI scales concerned with intrapersonal functioning (Sa and Wb), but the dry alcoholics did. This finding suggests that long-term recovered alcoholics, although socially inhibited, are relatively self-accepting, have a strong sense of well-being, and are free from excessive health concerns.

The findings reported in this study, although tentative, appear to have implications for both treatment intervention and the identification of areas of much needed research. Current research efforts have tended to focus on the identification of distinctive subgroups of personality types among diagnosed alcoholics and have emphasized the heterogeneous nature of the treatment population. The notable success of such research efforts has led to valuable suggestions concerning treatment intervention. Nerviano (1976), drawing on his extensive research with alcoholic patients, has suggested that treatment type and modality be adjusted to the individual alcoholic on the basis of identified personality typologies. The results reported here, while not directly concerned with the identification of personality subtypes, are consistent with this previous research and would further extend this suggestion to include a consideration of stage of recovery as an important factor in the determination of treatment modality and type. For example, one of the clinically most significant findings of this study was that the overall personality profile of the long-term recovered alcoholics differed significantly from both the newly recovered alcoholics and the nonalcoholic controls, suggesting a distinctive pattern of psychological adjustment among long-term recovered alcoholics. The most discriminatory dimension for differentiating between long-term recovered alcoholics and the other two groups was defined by (a) the general level of profile elevation, (b) an absence of psychoneurotic tendencies, and (c) poor interpersonal functioning. This finding would seem to strongly suggest that treatment intervention be adjusted to include stage of recovery as well as overall personality profile. Finally, the results reported here point to the need for more extensive and systematic research on the personality characteristics of long-term recovered alcoholics.

Cognitive Preparation and Coping Self-Talk: Anxiety Management During the Stress of Flying

Michel Girodo and Julius Roehl

University of Ottawa and The Royal Ottawa Hospital, Ottawa, Canada

The effectiveness of two cognitive coping strategies, singly and in combination, were investigated in 56 undergraduate females with a reported fear of flying. Subjects were assigned to four groups: preparatory information training, self-statement training, combined (information and self-talk), and pseudotreatment control and were flown aboard an 11-passenger Twin Otter aircraft for two flights. One half of the subjects flew with the door to the cockpit open, the other half flew with the door closed. Each flight encountered a planned unexpected missed landing. Self-reports of anxiety were obtained before takeoff, during the flight, and after landing. Even though the cognitive-coping strategies were not differentially effective in reducing anxiety during the ongoing stress of flying, under serious threat (unexpected event), with the cockpit door open, self-talk and combined subjects coped better than information and control subjects. With the door closed, all groups increased in anxiety. At final landing, with the door closed, self-statement-trained subjects increased in their self-reported anxiety. The results of a 4½-month follow-up on flight apprehension are discussed in light of the effects of the treatment manipulations.

Stress inoculation training (SIT) refers to a cognitive-behavioral treatment package (Meichenbaum, 1975) in which patients are taught to emit positive coping self-statements in learning how to cope with such stressors as pain (Turk, Note 1), test anxiety (Meichenbaum, 1972), and anger problems (Novaco, 1976). Basically, the SIT procedure involves (a) providing the subject with a theoretical framework or rationale for conceptualizing the effectiveness of self-talk in coping with a stress reaction; (b) teaching the subject a series of positive self-statements that focus on (i) preparing for a stressor, (ii) confronting and handling a stressor, (iii) coping with a feeling of being overwhelmed, and (iv) reinforcing oneself for having coped; and (c) trying out or rehearsing coping self-talk.

The authors are grateful for the assistance provided by Air Transit and the University of Ottawa for financial support in conducting the study.

Requests for reprints should be sent to Michel Girodo, School of Psychology, University of Ottawa, 1245 Kilborn Avenue, Ottawa, Ontario, Canada K1H 6K9.

Coping self-talk procedures have also been used in connection with the reduction of psychological stress in surgical patients by Langer, Janis, and Wolfer (1975). In this study, patients who were taught cognitive reappraisal of anxiety-provoking events and were induced to engage in calming self-talk and attention diversion coped better with pre-surgery and postsurgery stresses than did the subjects who were given preparatory information designed to induce "work of worrying" and subsequent emotional inoculation for the stressor (Janis, 1958, 1971). Although the preparatory information increased arousal, this effect dissipated over time, and no evidence of positive postoperative effects were found. These results are in contrast to the findings of Melamed and Siegel (1975), who studied the effects of filmed modeling in reducing anxiety in children facing hospitalization and surgery. The results of this study support the contention that a moderate amount of arousal prior to the stressor may facilitate coping with the stressor once it presents itself.

Another way of looking at the work of worrying process focuses on the notion that the

beneficial effects of engaging in work of worrying are obtained when the person engages in anticipatory problem solving and cognitive rehearsal of coping with the forthcoming stressful event (Meichenbaum, 1975). The suggestion is that the individual experiences a moderate level of arousal when covertly rehearsing the handling of a stressful situation, and this prompts the emotional inoculation necessary to help the person cope better with the stressor.

The general purpose of the present experiment was to assess the applicability of the SIT procedure and preparatory information in coping with a real-life stressor. Specifically, the experiment sought (a) to examine the relative effectiveness of (i) the SIT procedure and (ii) preparatory information, singly and in combination, in coping with a flying experience among persons who were apprehensive of flying; (b) to study the effects of these treatment procedures over two trials; and (c) to examine the effects of an additional stressor in the form of an "unexpected missed landing" on coping ability. It was felt that an unexpected stressful event during the flight might provide the needed variation to demonstrate greater differential effectiveness of one treatment over the other.

An additional feature of the experiment concerned whether subjects had visual access to the pilot and copilot in the cockpit area. In this regard, it was hypothesized that subjects who received preparatory information in the form of reliance on "danger control authorities" would experience less anxiety under conditions in which such figures were visually present and salient, compared to preparatory information subjects who did not have access to such visual information and external reassurances. It was predicted that subjects trained in the SIT procedure would not be as reliant on danger control authorities or on seeking external reassurances compared with individuals given preparatory information, and, as such, that they would be less susceptible to the effects of the availability or nonavailability of these external cues.

Method

Subjects

Subjects were 56 female undergraduate students ranging in age from 18 to 34 ($M = 21$). They were

selected on the basis of four screening questionnaire criteria: (a) They scored 6 or more on a 10 point scale designed to assess flight apprehension (i.e., "How do you usually feel while flying in an airplane?" Very calm and relaxed served as the anchor at one end, and very nervous and tense provided the anchor at the other end). (b) They had previously flown (M no. flights = 5.48). (c) They had never flown in the particular type of aircraft used in the present experiment. (d) They had indicated on the screening questionnaire that they would be willing to serve as a subject in an experiment that involved flying. The screening questionnaire was completed by 1,526 male and female students enrolled at the University of Ottawa, Carleton University, and Algonquin College. Of these, 92 females met the four selection criteria.¹ These subjects were contacted on a random basis and were scheduled for participation on 1 of 6 weekends according to their availability.

Aircraft and Apparatus

The aircraft in which subjects were flown consisted of a DeHavilland Twin Otter with a capacity of two crew and 11 passengers. This short takeoff and landing (STOL) aircraft takes off and lands using a 1,500 foot (457.2 m) runway at a 6-degree angle (compared with the conventional 3-degree slope). In addition to standard-specialized avionics, the STOL aircraft was equipped with a computerized air data acquisition system, which recorded 43 performance parameters of the flight. Of interest to study for possible covariate analysis were measures of turbulence in the form of vertical deviation scores obtained every 2 sec. Earphones and a hand-held microphone were installed at the rear of the cabin to allow for constant communication between the cockpit area and the experimenter. A sliding door served to separate the pilot and passenger area for half of the flights. The seating in the STOL was the same as that found in modern passenger aircraft, with five seats on the left and six seats on the right of the aircraft.

Design

Four training groups of 14 subjects each were exposed to one of four treatments or treatment combinations. One group of subjects was exposed to preparatory information; a second group, to the SIT procedure (self talk); a third group, to a combination of the information and self talk treatments (combined); and a fourth group of subjects was exposed to films on the history of aviation (control).

Subjects were seen in small groups for training on the Saturday preceding the Sunday flight. All subjects participated in two flying trials, the first involving a 45-minute flight from Ottawa to Montreal with a 20-minute stopover, followed by a second identical trial returning to Ottawa. Subjects in the same treat-

¹ The distribution of scores for the 943 females had a mean of 3.0 with a standard deviation of 2.8. The cutting score of 6 ($z = 1.29$) represented the upper 10% of the population.

ment groups were assigned seats behind each other on the same side of the aircraft. This served to reduce possible social comparison processes; persons visible to any one subject were essentially strangers in a different treatment condition. All subjects flew during both trials with either the door open or closed. Measures of self-report of anxiety were obtained at six points throughout the first trial: during "rev up"; after takeoff; following 10 minutes, 20 minutes, and 30 minutes of cruising; and after landing. On Trial 2, an additional measure of self-report of anxiety was obtained following the "missed approach." Thus, this formed the basis of a 4 (groups) $\times 2$ (door) $\times 2$ (trials) $\times 6$ or 7 (assessment periods) factorial design.

On the second trial, the missed landing occurred as follows: In its final approach into Ottawa, the aircraft descended in a normal landing pattern to an altitude of 100 feet (30.4 m). At this point a stall-warning horn sounded in the cockpit, the pitch of the propellers was changed, and full power was applied to the engines. The aircraft rose rapidly, banking to the left until it reached an altitude of 2,000 feet (609.6 m). At this point, the captain apologized for the missed approach, explaining that a light aircraft was taxiing onto the runway without authorization from the control tower and that they would be making a normal landing in about 5 minutes.

Procedure

Instructions and specific training procedures were delivered primarily via audio tape recorder. All subjects were assured that their responses would be kept confidential and that no harm would come to them in the normal course of the experiment. The experimenter also requested that subjects not disclose details of the experiment to anyone until they had received a statement in the mail describing the purpose and results of the experiment and the role they had played. Following this, subjects were asked to complete a self-report of anxiety inventory (SRAI) and the initial flight apprehension inventory (FLAPI) and were asked to sign a consent form.

Self-Talk Training

This 2½-hour training procedure attempted to follow as closely as possible the descriptions given by Meichenbaum (1975) in outlining the SIT procedure. Briefly, as part of this training, the experimenter stressed the importance of learning positive self-statements as a method for coping with stress. All subjects were asked to share with other members in the group events in which they experienced nervousness or anxiety and to recall the negative thoughts that accompanied these situations. Through a tape recording, the conceptual rationale of the SIT and a list of positive self-statements in the four phases of coping with a stressor were presented. Taking a slow deep breath was presented as a effective strategy for dealing with the physical component of anxiety, and positive coping self talk was presented as the strategy for handling the cognitive component of anxiety. The tape continued with an example of a person taking an exam in which negative

self-statements and feelings of anxiety were present, followed by instructions that negative self-statements and anxiety feelings should serve as cues for emitting positive-coping self-statements. Following this, subjects were given a prepared list of coping self-statements (Meichenbaum, 1975). They were then instructed to imagine a stressful situation, to prepare their own list of coping self-statements, and to memorize this list. Following a 10-minute learning period, subjects were tested on their recall of the self-statements. To further consolidate the training procedure, the tape continued with a description of an imaginary horseback ride for a person who was fearful of horses. Subjects were asked to fantasize and imagine clearly a person making positive coping self-statements as the horse was approached, touched, mounted, ridden, and dismounted after a successful riding experience. Following this exercise, subjects were asked to share with other members of the group their individual self-statements, and each subject compiled the final list of positive self-statements that she was to use when flying the next day. Subjects were instructed to rehearse making positive coping self-statements in anticipation of the flight of the following day.

Preparatory Information Training

As in the self-talk training, this procedure began with the same request for a discussion of events in which subjects experienced nervousness or anxiety. Following this, the experimenter expressed the importance of acquiring prior information about potentially stressful events as a method for coping with stress. The experimenter then illustrated the effectiveness of prior information for coping with test anxiety. A tape recording then described the theoretical rationale of this training procedure, drawing examples from the scientific literature (e.g., Janis, 1958, 1971). The audiotape continued with a detailed description of the events that were to take place the following day. This description included the nature of the transportation to the airport, the preboarding procedures, the exterior and interior of the aircraft, and the takeoff and landing procedures. Twelve colored slides depicting the STOLport, aircraft, a view from the ground over the two cities and during cruising, takeoff, and landing were shown at appropriate points in the presentation. To have the subjects view the pilots as "danger control authorities," descriptions of the pilots' training and experience with emphasis on their skill, expertise, maturity, and 20 years of service were given. To control for time with the experimenter, the above presentation was given twice.

Combined Training

This training procedure consisted of a 3½-hour combination of the SIT and preparatory information procedures. To control for equal time with the experimenter, the information procedure was presented once.

Pseudotreatment Control

In this condition, as in the other three treatments, subjects spent an initial period of time sharing with the group how they felt and what they thought of when in a stressful situation. This was designed to control for possible effects associated with ventilation of affect related to fears. Following this, subjects were shown three 20-minute films depicting the history of aviation in Canada. Following the film presentations, subjects were asked to relate to the group what they liked least and most about each film. Thus, time with the experimenter and interaction time among subjects was equivalent across all conditions.

To reduce time spent completing scales on the day of the flight and after training, subjects in all groups were given specific instructions and practice with the SRAI that they would be using the following day. Subjects were instructed not to talk to each other at any time at the STOLport or throughout the flight.

Dependent Measures²

The SRAI served as the chief dependent measure in the experiment. This inventory consisted of four 11-point scales anchored at each end from very to not at all, and was designed to measure cognitive and somatic components of anxiety after the symptom clusters of Buss (1966). The four scales measured (a) calm and relaxed; (b) worried and apprehensive; (c) anxious and nervous; and (d) tense and trembling. Item analyses correlating each scale score with total scale score revealed that essentially the same construct was being tapped, consistent with coefficients obtained in previous studies (Girodo, 1974).

The SRAI was administered prior to training, immediately following training, at the training site, the morning of the flight at the STOLport prior to boarding, during the rev up, following takeoff, after three 10-minute cruising periods, following the unexpected event on Trial 2, and after landing. The SRAI was modified slightly on several of these occasions to coincide with the events that had just transpired. Thus, although subjects were generally asked to indicate how they felt at present, the estimates obtained for the three 10 minute cruising periods asked the subjects to indicate how they had felt during the last 10 minutes or how they had felt as a result of the takeoff, the unexpected event (see below), and the landing. Another modification asked, "How have you been feeling since yesterday afternoon in anticipation of the flight today?" Subjects used the SRAI scales to reply to this item when they met at the training site on the morning of the flight. Following the missed approach, the experimenter stated that he wanted to take advantage of the situation and record reactions on an additional questionnaire. This he did by distributing an untitled SRAI and verbally requested the subjects to indicate on the scales provided how they had felt as a result of what had just happened.

Treatment effectiveness questionnaire. This consisted of an eight-item postexperimental questionnaire designed to measure the effectiveness of self-statements in coping with the stress of flying. Here, self-talk and

combined group subjects were asked to (a) list the self-statements that they emitted during the flight; (b) indicate the percentage of time that they used self-talk, and (c) rate the effectiveness of self-talk as a coping device on an 11-point scale ranging from not as helpful and useful at one end to very helpful and useful at the other end. Subjects in the information condition were asked to (a) rate the effectiveness of the information given to them on a similar 11-point scale in helping them cope with the stress and (b) indicate what kind of information might have been beneficial to them in coping with the flight.

Follow-up

A follow-up letter and questionnaire were mailed to all subjects 4½ months after the conclusion of the experiment. Although this was designed to assess any negative or untoward effects of participating in the experiment, it also inquired into the current flight apprehension of subjects by repeating the FLAPI, given at the time of initial screening.

Results

Training and Preflight Assessment

An analysis of variance performed on SRAI scores obtained immediately after training indicated that treatment manipulations produced significant differences in self-report of anxiety between groups, $F(3, 52) = 8.83$, $p < .001$. Tukey tests indicated that both self-talk and combined subjects reported significantly more anxiety ($p < .05$) immediately after training compared with subjects in the control and information conditions. The scores obtained on the SRAI the morning of the flight at the training site failed to yield significant group differences; however, the results obtained by using the Duncan's multiple-range test (Duncan, 1955) suggested that self-talk subjects were still slightly more aroused than information subjects ($p < .05$). A similar analysis of SRAI scores obtained at the STOLport prior to departure yielded a similar non-significant F ; however, again Duncan's test revealed that self-talk subjects were slightly more aroused than subjects in the combined group ($p < .05$).

² At the STOLport, electrodes were attached to the subjects' wrists and left ankle to record heart rate on cassette. Equipment problems early in the experiment forced the experimenter to abandon this measure; however, electrodes were still applied to all subjects on the remaining flights.

Table 1

Means and Standard Deviations of Self-Report of Anxiety Inventory (SRAI) Scores at Pretraining and Posttraining and Work of Worrying Scores on Flight Day

Group	SRAI				Work of worrying scores	
	Pretraining		Posttraining		<i>M</i>	<i>SD</i>
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>		
Information	11.65	7.67	6.43*	4.18	8.60	4.86
Self-talk	14.29	6.93	14.36	6.42	15.50**	5.00
Combined	17.21	7.81	12.29	7.26	8.14	5.33
Control	13.43	7.71	5.29*	3.52	8.29	5.20

* $p < .05$; significant decreases from pretraining to posttraining.

** $p < .001$; significantly greater than mean scores from other groups.

An analysis of variance performed on the flight anticipation scale that asked how subjects had been feeling since yesterday afternoon in anticipation of the flight showed a significant treatment group effect $F(3, 52) = 6.96$, $p < .001$. Tukey tests indicated that self-talk subjects reported engaging in significantly more work of worrying than subjects in the other three groups. Table 1 summarizes the results of the SRAI and "worry" scales for these preflight assessments.

Flight Assessment

It was found that although turbulence did take place and was perceptible by the pilots, it had no significant effect on SRAI reports.³

Trial 1. A 4 (groups) $\times 2$ (door) $\times 6$ (assessment periods) analysis of variance on the SRAI scores yielded a significant effect for assessment periods, $F(5, 48) = 35.96$, $p < .001$. Treatment groups did not differ from each other at either rev up, takeoff, following each of the three 10-minute cruising periods, or during landing. An analysis of variance on the Groups \times Door \times Cruising Periods produced a main effect for cruising periods, $F(2, 48) = 8.31$, $p < .001$. A main effect for the door condition was obtained for the third cruising period, $F(1, 48) = 4.73$, $p < .03$, and Tukey tests revealed that subjects who flew with the cockpit door open reported significantly more arousal ($p < .01$) than subjects who flew with the door closed. No SRAI differences were found between groups for the door condition for the first landing.

Trial 2. A $4 \times 2 \times 7$ analysis of variance on SRAI scores produced a main effect for the door condition, $F(1, 48) = 5.48$, $p < .03$, and a main effect for assessment periods, $F(5, 48) = 47.69$, $p < .001$. An analysis of variance considering only the treatment groups and the rev up and takeoff periods failed to produce significant differences. An analysis of variance on the groups, door condition, and three cruising periods yielded a significant effect for door, $F(1, 48) = 8.90$, $p < .004$, and for cruising periods, $F(2, 48) = 11.46$, $p < .001$. Even though treatment groups did not differ from one another at any of the cruising periods, subjects in the door open or door closed conditions differed significantly from each other after the first 10 minutes, $F(1, 48) = 10.32$, $p < .003$; following 20 minutes of cruising, $F(1, 48) = 5.90$, $p < .02$; and following 30 minutes of cruising, $F(1, 48) = 8.20$, $p < .006$. Figure 1 illustrates the nature of these findings.

Subjects who flew with the door open reported significantly more arousal than subjects who flew with the door closed when confronted by the unexpected event, $F(1, 48) = 4.25$, $p < .04$. At final landing, however, no significant overall differences were found between door open or door closed conditions.

Since the door conditions produced significant differences in SRAI scores, separate post hoc analyses were performed on the third

³ A complete report on the way the air data acquisition system and crew reports of turbulence were treated in analyses of covariance is available from the first author.

Figure 1. Mean self-report of anxiety inventory scores for subjects in the door open and door closed conditions across flight events for the second trial.

cruising period, the unexpected event, and the final landing. Figure 2 plots the SRAI scores for subjects in the treatment groups across these three periods for door open and door closed conditions.

When the door open condition is examined, it can be seen that significant differences between self-talk subjects and control subjects were obtained during the unexpected event, $t(12) = 3.10$, $p < .009$. Again, in the door open condition, the changes in SRAI scores from the last cruising period to the unexpected event were examined by correlated t tests. It was found that the SRAI scores of subjects in the control condition and in the information condition significantly increased from the last cruising period to the unexpected event, $t(6) = 4.99$, $p < .02$, and $t(6) = 3.39$, $p < .002$, respectively. Even though there was a tendency for the scores of both self-talk and combined group subjects to increase, this was not statistically significant. From the unexpected event to the landing, all groups tended to show decreases in their self-report of anxiety; however, only the control subjects' scores de-

creased significantly from the unexpected event to the landing, $t(6) = 2.53$, $p < .05$.

In the door closed conditions, the scores of subjects in all four treatment groups increased significantly but not differentially. Considering the SRAI scores from unexpected event to landing, correlated t tests revealed that although the SRAI scores of the control group subjects decreased significantly, $t(6) = 2.48$, $p < .05$, together with a nonsignificant tendency for the scores of the combined group subjects to decrease, the scores of self-talk subjects actually *increased* from unexpected event to landing, $t(6) = 4.58$, $p < .004$. Information subjects showed a nonsignificant increase in self-report of anxiety.

In view of the wide variability of the data at each of the plotted points, complex chi-square analyses were performed on the number of subjects whose scores decreased as opposed to those whose scores stayed the same or increased. From the last cruising period to the unexpected event, scores for *all* subjects except one (self-talk, door open) increased, $\chi^2(3) = 3.06$, ns ; however, differential changes in SRAI

Figure 2. Mean self-report of anxiety inventory scores for subjects in the four treatment groups, in door open or closed conditions, at the last cruising period, the unexpected event, and the final landing. (From *Stress and Anxiety* (Vol. 4) by I. G. Sarason and C. D. Spielberger (Eds.), 1977. Copyright 1977 by Hemisphere. Reprinted by permission.)

scores from unexpected event to landing were obtained, $\chi^2(3) = 18.89$, $p < .005$, in that scores of 11 of the 14 subjects in the control group and 11 of the 14 subjects in the combined group decreased from unexpected event to landing, whereas only 3 of the 14 self-talk subjects and 7 of the 14 information subjects obtained lower SRAI scores from unexpected event to landing. When the door conditions were examined for chi-square differences, only the door closed chi-square obtained differences in number of subjects who either increased or decreased from unexpected event to landing, $\chi^2(3) = 15.43$, $p < .02$. Here, 5 of 7 control subjects and 5 of 7 combined subjects showed decreases in anxiety, whereas only 3 of 7 in-

formation subjects and none of the self-talk subjects reported decreases in anxiety. Fisher's exact test (Fisher, 1966) revealed that there were significantly more control (5) and combined (5) subjects' SRAI scores that decreased compared with none of the subjects in the self-talk group, $\chi^2(3) = 7.69$, $p < .05$.

Seating. An analysis was undertaken for subjects seated in the first four seats nearest the cockpit and the remaining six seats to the rear of the aircraft. On Trial 1, a Group \times Door \times Seating analysis of variance failed to reveal any significant effect for seating or any interaction between seating and the door or group condition. Similar nonsignificant effects for seating were obtained on SRAI scores for

Trial 2. However, a significant Group \times Seating interaction was obtained for the landing on Trial 2, $F(3, 40) = 4.39$, $p < .009$. Tukey tests showed that at the final landing, information group subjects who sat in the front of the aircraft reported the lowest SRAI scores, whereas information subjects seated in the rear reported the highest SRAI scores. Subjects in the combined group and in the self-talk group who were seated in front had higher SRAI scores than subjects in those groups who sat in the rear of the aircraft. Control group subjects did not differ significantly in terms of their assigned seating. It was interesting to find that these effects were only slightly amplified (but not significantly) in the door open as opposed to the door closed condition.

Postexperimental Questionnaire

In reply to the question "Do you wish you had acquired more information and known better what to anticipate today?", seven of 14 control subjects expressed the need for more information, compared with 2 of 14 information subjects and 2 of 14 combined subjects, $\chi^2(2) = 6.16$, $p < .05$. Fisher's exact test revealed that more subjects in the information group (12) expressed satisfaction with the amount of information that they had acquired prior to the flight compared with subjects in the control group (7) ($p < .05$). When subjects were asked to rate how effective they had found the techniques of providing information about what to anticipate in helping them cope with the stress of flying, no differences were found between subjects in the door closed condition. However, subjects in the door open condition differed significantly in their ratings on this question, $F(2, 18) = 12.12$, $p < .001$. Tukey tests revealed that information and combined subjects did not differ in their rated effectiveness of acquiring information as a coping device. However, control subjects rated the information that they had acquired as significantly less effective in coping with stress compared with information or combined subjects ($p < .05$). The self-talk and combined subjects, overall and in both door conditions, did not differ on the percentage of time that they had spent emitting positive self-statements. The subjects' ratings on the

effectiveness of emitting positive self-statements in coping with the stress of flying also revealed no differences between these two groups. A significant positive correlation ($.61$, $p < .001$) was obtained between the reported percentage of time that subjects spent making positive self-statements and the rated effectiveness of their making self-statements in coping with the flight experience. Also, positive correlations were obtained between SRAI scores at various assessment periods and the reported percentage of time spent making positive self-statements. Specifically, positive correlations between anxiety scores and self-statement use were obtained at the third cruising period for Trial 1 ($r = .34$, $p < .04$), at the first landing ($r = .32$, $p < .05$), and for the unexpected event ($r = .33$, $p < .04$). No significant correlations were obtained between SRAI scores at each of the assessment periods and the reported effectiveness of self-talk.

Follow-up

Fifty-three of 56 (95%) follow-up questionnaires mailed 4½ months after the study was completed were returned. Subjects in all four treatment groups reported significantly lower flight apprehension scores at follow-up compared with their pretraining scores. For subjects who were in the door open condition, the information, self-talk, and combined groups, $t_s(6) = 3.58$, 4.46, and 4.70 ($p < .01$), respectively, reported significant decreases in their FLAPI scores, whereas control group subjects failed to show any significant change in their FLAPI scores from pretraining to follow-up. For subjects in the door closed condition, t tests on change scores revealed significant decreases in flight apprehension for self-talk subjects, $t(6) = 6.30$, $p < .001$; and combined subjects, $t(6) = 3.12$, $p < .03$. Subjects in the information and control conditions did *not* report significant changes in FLAPI scores. Thus, subjects who were exposed to self-statement training (self-talk and combined) reported significant reductions in flight apprehension 4½ months after the experiment regardless of the condition that they were in. It is of interest to note that subjects in the control group failed to show significant decrements in flight apprehension from pretraining to follow-up, especially in view of the

fact that their SRAI scores were markedly similar to those of the treatment groups at various points throughout the two trials.

Discussion

The major findings of the experiment were as follows: (a) Generally, subjects who flew with the door open showed more anxiety than subjects who flew with the door closed. Even though all subjects tended to decrease in anxiety in the form of possible habituation effects (e.g., Solyom, Shugar, Bryntwick, & Solyom, 1973), door closed subjects habituated more rapidly than door open subjects. (b) The various treatment manipulations generally failed to demonstrate differential coping effectiveness throughout the normal course of the flights. (c) The additional stressor, in the form of an unexpected event, produced differential increases in anxiety when the cockpit door was open, in that self-statement-trained subjects coped better than information and control subjects. This was not the case in the door closed conditions in which self-talk subjects did not cope with the subsequent landing as well as subjects in other groups.

Work of Worrying

No evidence was found to support the hypothesis that preparatory information served to increase arousal levels either immediately after training or prior to the flight. Only SIT-trained subjects reported significantly high levels of anxiety immediately following training as well as prior to the flight itself. Also, self-talk subjects also reported greater amounts of "worry and apprehension" during the 20 hours preceding the flight. It is interesting to note that combined subjects who also received self-statement training did not manifest the same increase in arousal following, nor did they report greater work of worrying, prior to the flight. Conceivably, self-talk subjects may have rehearsed coping self-statements, in connection with imaginary and nonspecific flight events, unlike the combined subjects who may have rehearsed their self-talk with predictable events and images depicted on the slides. Whatever the effects of satisfactory worry/cognitive preparation on coping with a

future stressor may really be, they were not obtained in the present study: Recall that both self-talk and combined subjects coped comparatively well with the unexpected event in spite of the fact that combined and information subjects failed to reveal any indication of anticipatory anxiety.

Door Open Condition

As might be expected, preparatory information seemed to be ineffective in coping with an unexpected missed landing, and subjects in this condition responded to stress with increases in anxiety similar to the control subjects. Also, even when danger control authorities were visible, information subjects did not appear to find their visible presence a source of reassurance to allay their anxieties.

Door Closed Condition

Here, it appears as if not having visual contact with the cockpit area can account for the reasons that the treatment groups significantly increased in anxiety from the last cruising period to the unexpected event. It appears that in the door closed condition, the importance of being able to process information about the significance of a stressor may take precedence over any attempted coping strategy. Conceivably, being able to monitor what is happening or to be able to answer questions one is raising concerning the significance and importance of an unanticipated event may have an overriding influence, and no amount of self-talk will serve to distract the individual from this information search process.

The effects of seating arrangement appeared to be most salient for the information group. Subjects in the information group seated in the front of the aircraft reported the lowest SRAI scores of all treatment groups, and the information subjects seated at the rear obtained the highest scores. At first glance it would appear as if subjects exposed to the information coping strategy were better able to cope with the second landing if they were able to process information, confirm expectations, and rely on cues from danger control authorities for obtaining reassurance. However, this seating effect on information subjects was obtained in *both* the door open and

door closed conditions. Although this is somewhat puzzling, it could suggest that physical proximity from such danger control authorities is a more important variable than the availability of visual contact with such figures when it comes time to cope with such a stressor. It is interesting to note that since the effect of proximity to the cockpit area was not obtained for subjects given other coping strategies, subjects given preparatory information could have been excessively reliant on this coping strategy in coping with the stress of the second landing.

The seating factor only became significant for the information subjects during the second landing. This is understandable if we consider that it is only after the missed landing that these subjects felt an additional stress in the sense of a disconfirmation of the expectancies induced by the preparatory information treatment package. Possibly because they could no longer rely on the information presented to them concerning what to anticipate, these subjects may only at that time have felt a need for reassurances or for proximity to danger control authorities.

The follow-up data suggest that the SIT and preparatory information procedures singly or in combination were equally effective in reducing flight apprehension 4½ months later. This was true only for subjects who flew with the cockpit door open, since only subjects trained in the SIT procedure who flew with the door closed reported long-term decrements in flight apprehension. The fact that door closed/information group subjects did not report lowered flight apprehension at follow-up may relate to an assertion by Averill (1973) in connection with perceived control over aversive events. He suggested that even though information about a stressor may have value in helping a person cope with a stress, it may only be effective if it is validated by experience and if such information was found to be veridical in reducing objective worry following reality testing. It may not be too surprising, therefore, to have found that preparatory information was not useful in producing long-term decrements in flight apprehension especially when access to sources of reassurance was cut off and after expectations concerning the flight events were disconfirmed.

Theoretical Considerations

Two important theoretical issues are raised by the results of the present investigation. First, looking only at the anxiety scores obtained during the two cruising periods, the absence of any evidence of a differential coping ability across treatment groups suggests that the SIT procedure is no more effective for coping with the ongoing stress of flying than preparatory information or when persons are left to their resources (i.e., control). These findings cast some doubt on the theoretical underpinnings of the SIT procedure, specifically on the assertion that the act of emitting positive self-statements in the presence of a stressor can effectuate anxiety reduction.

The second theoretical issue concerns the mediating role of cognitions in altering emotional reactions. Since, in the present experiment, self-talk/door open subjects did not increase in anxiety during the unexpected event, and since the anxiety scores of all seven of the self-talk/door closed subjects increased from the unexpected event to the final landing, the issue does merit some attention. We can focus on the specific question, "What cognitive processes can explain the mediating role of self-talk in stress reactions?" First, it might be useful to determine what processes are probably not involved before trying to arrive at an understanding of what they might be. If we look at the semantic therapies of Beck (1970) and Ellis (1962), for example, a common denominator of cognitive reorganization serves as the foundation for coping and emotional adjustment. Whether it be the correction of arbitrary inferences or selective abstractions in the former, or the changing of irrational beliefs and assumptions in the latter, both cognitive therapies work at the level of the person's epistemological base for creating new perceptions and understandings. As has been explained elsewhere (Girodo, 1977), in spite of certain similarities, the crucial cognitive processes in the SIT procedure may have very little to do with modifying the subject's epistemological base. When subjects "buy" the persuasive conceptual rationale of the SIT package, this does not necessarily cast the die for producing emotional responses simply by repeating their semantic equiva-

lents. Indeed, as was found in a coping with pain study by Girodo and Wood (Note 3), the persuasive rationale serves more to motivate subjects to use the self-talk technique rather than to reorganize cognitions that would make the stressor less painful. Inasmuch as attentional processes were implicated in producing differential coping responses in the SIT pain experiment, we felt that it might be more than simple conjecture to suggest that similar attentional processes might be involved in SIT subjects' responses to the unexpected event and subsequent landing.

What is it about monitoring internal states and repeating self-statements that had such a detrimental effect on SIT door closed subjects during the final landing? Although it is conceivable that these subjects abandoned their self-talk strategy after the unexpected event (possibly because it may have failed them when it was most needed), an alternative explanation along the lines proffered by Sarason (1975) is more compelling. He suggested that self-preoccupation involves the kind of attentional activity that can interfere at a variety of points with information processing and subsequent planning strategies for coping with a stressor. The conditions for increased self-preoccupations were present in the self-talk treatment in that subjects were exposed to (a) a door closed condition in which cockpit and pilot reassurance cues were not available and (b) an indoctrination to a self-statement strategy that forced subjects to attend mainly to their internal state. We propose that this kind of induced self-preoccupation may have interfered with information processing and evaluation necessary in the planning of a coping strategy for dealing with the uncertainty of the second landing. Why this increase in anxiety at the final landing was not manifested in combined subjects is difficult to explain unless we assume that the reassurances concerning pilot competency had an appropriate effect then.

Finally, recall that significant positive correlations were obtained between the reported percentage of time that subjects were making positive self-statements and their anxiety scores at three of the assessment periods. In light of (a) the previous arguments suggesting that forced self-talk may interfere with appraisal and coping processes, (b) the finding

that two of these correlations were obtained for stressors that would normally invite information processing and/or appraisal processes (i.e., the first landing and the unexpected event), and (c) the absence of a significant correlation between the subjects' rated effectiveness of the SIT procedure and their anxiety scores, it is reasonable to suggest that the more time subjects spent making their self-statements, the more anxious they became at various points of the flying experience.

In conclusion, we would like to draw attention to the distinction between semantic therapies that work on inducing new beliefs or correcting cognitive distortions, and thus produce emotional change via this epistemological base, and the self-talk therapy in which the mediating processes may be more inimical. We should not lose sight of the fact that the conceptual rationale underlying the SIT procedure is designed to induce the subject to comply with self-talk instructions and that they are given for *his or her* benefit, and not for the therapist to come to believe. On the basis of the present experiment, we suggest that if indeed attention information-processing demands mediate in SIT-produced emotional reactions, then these can be viewed as methodological artifacts of the semantic therapy. On the one hand, maybe we better not let patients in on this, for it may be only because they believe that their positive self-talk can produce their semantic equivalent that they cope better on occasion. On the other hand, we should not forget that the self-talk may be applied so faithfully that it interferes with the use of other available coping mechanisms.

Use of Electromyographic Biofeedback and Cue-Controlled Relaxation in the Treatment of Test Anxiety

D. Kenneth Counts, James G. Hollandsworth, Jr., and John D. Alcorn
University of Southern Mississippi

The effect of using electromyographic (EMG) biofeedback to increase the efficacy of cue-controlled relaxation training in the treatment of test anxiety was studied. Forty college undergraduates scoring in the upper third on a self-report measure of test anxiety were randomly assigned to one of four treatment conditions—EMG-assisted cue-controlled relaxation, cue-controlled relaxation alone, attention-placebo relaxation, and no-treatment control. Pre-post self-report measures of test anxiety, state anxiety, and trait anxiety were obtained. In addition, a performance measure in the form of a mental abilities test was administered. Subjects from the three relaxation groups received six 45-minute individual sessions over a period of 2 weeks. All treatments were conducted using audiotape recordings. The results indicate that cue-controlled relaxation is effective in increasing test performance for test anxious subjects, that EMG biofeedback does not contribute to the effectiveness of this procedure, and that self-report measures of anxiety are susceptible to a placebo effect.

The use of relaxation training in the treatment of test anxiety has met with mixed results (Chang-Liang & Denney, 1976; Johnson & Sechrest, 1968). Of primary concern has been the generalization of the relaxation response to stressful situations occurring beyond the confines of the treatment room itself (e.g., Goldfried & Trier, 1974). Modifications of the basic technique, such as cue-controlled relaxation, appear to facilitate this generalization process (Russell & Sipich, 1973). Furthermore, the use of other aids, such as electromyographic (EMG) biofeedback, may increase the effectiveness of relaxation training itself (Haynes, Moseley, & McGowan, 1975). Until now, however, there has been no investigation of the relative contribution of each of these procedures toward improving the test performance of test anxious students.

The technique of cue-controlled relaxation

was first presented as a possible treatment for test anxiety by Russell and Sipich (1973). This approach consists of deep muscle relaxation training and the pairing of a cue word such as "relax" or "calm" with breath exhalation while relaxed. According to the classical conditioning paradigm, after a number of these pairings, the cue word alone should elicit relaxation and a feeling of calmness. Two case studies (Russell & Sipich, 1973, 1974) have provided support for the use of cue-controlled relaxation in treating test anxiety. Russell, Miller, and June (1974) also used group cue-controlled relaxation in the treatment of test anxious college students. Even though the results were encouraging, no control group was included and the dependent measure was restricted to self-reports. A comparison of cue-controlled relaxation with systematic desensitization (Russell, Miller, & June, 1975) indicated that the two treatments were equally effective. Both treatment conditions were superior to the control group on self-report measures, but no differences were noted on the performance measure. Another comparison of these treatment conditions obtained equivocal results (Russell, Wise, & Stratoudakis, 1976). Marchetti, McGlynn, and

The authors would like to thank Robert E. Agnew for his valuable assistance on preparing the treatment tapes.

Requests for reprints should be sent to James G. Hollandsworth, Jr., Department of Counseling Psychology, University of Southern Mississippi, Box 272 Southern Station, Hattiesburg, Mississippi 39401.

Patterson (1977), however, found that the effects of cue-controlled relaxation failed to exceed those of a placebo or no-treatment condition on self-report measures and psychophysiological indices of arousal during test taking.

In recent years, EMG biofeedback training also has gained popularity as a relaxation training method. Essentially, the client receives feedback (auditory, visual, or both) on the amount of tension in the monitored muscle group. This feedback facilitates the relaxation process. Haynes et al. (1975) compared the effectiveness of frontalis EMG biofeedback and two types of verbal relaxation instructions in reducing muscular tension. EMG biofeedback was equal to one form and superior to the other form of verbal instructions. Similar results were found by Reinking and Kohl (1975). Canter, Kondo, and Knott (1975) found EMG biofeedback superior to verbal instructions in reducing tension and concomitantly relieving anxiety symptoms in adult psychiatric patients.

The particular sensory mode of the feedback may be important in EMG relaxation training. Alexander, French, and Goodman (1975) compared the efficacy of auditory and visual feedback in EMG biofeedback training. The results indicated that auditory feedback may be more effective in the induction of muscular relaxation than visual feedback.

The use of EMG biofeedback in conjunction with various behavioral treatment strategies has yielded encouraging results. In one study (Wickramasekera, 1972), EMG biofeedback was used in the relaxation phase of the systematic desensitization of test anxiety. The procedure was supported by decreases in client reports of test anxiety. Reeves and Mealiea (1975) used EMG-assisted relaxation in the cue-controlled relaxation treatment of flight phobia. Even though the Reeves and Mealiea study was without adequate controls, the results indicate that this method has considerable promise as a treatment strategy for a wide range of disorders.

At this point, the majority of research on cue-controlled relaxation with test anxiety has either lacked performance measures, control conditions, attention-placebo conditions, or a combination of these factors. Furthermore, a

controlled investigation of the combination of EMG biofeedback with cue-controlled relaxation training has not been reported.

This study was designed to investigate the effectiveness of EMG-assisted cue-controlled relaxation in the treatment of test anxiety. More specifically, it was hypothesized that test anxious subjects receiving cue-controlled relaxation training or EMG-assisted cue-controlled relaxation training would report less test anxiety and demonstrate a greater increase in test performance than subjects receiving an attention-placebo treatment or no treatment. Furthermore, it was hypothesized that test anxious subjects receiving EMG-assisted cue-controlled relaxation training would report less test anxiety and would demonstrate a greater increase in test performance than subjects receiving the cue-controlled relaxation procedure alone.

Method

Subjects

The Test Anxiety Scale (TAS) was administered to 294 undergraduate students midway through the academic quarter. These students were unaware that high scorers would be given the opportunity to receive treatment for test anxiety. This sample generated a TAS mean score of 16.85 with a standard deviation of 7.97. Sixty-nine students who received a raw score of 21 or above, which placed them in the upper third of the distribution, were contacted by telephone and were asked to participate in the study. A total of 47 subjects were pretested and stratified according to the TAS and Otis-Lennon performance test results. Subjects within each stratum were randomly assigned to one of four treatment conditions—EMG-assisted cue-controlled relaxation, cue-controlled relaxation, attention-placebo, or no-treatment control. Seven of these 47 subjects failed to complete treatment, with the two treatment groups losing 2 each and the attention-placebo group losing 3. As a result, the final sample consisted of 40 subjects, 10 in each group, with a mean age of 20.6 years, ranging from 16 to 35. There were 28 females and 12 males. Most of the subjects were either freshmen or sophomores. Subjects received academic credit for participating in the study.

Apparatus

Subjects received treatments in a dimly lit, air-conditioned, sound-attenuated room in which there was a reclining chair, cassette tape recorder, EMG biofeedback device, small table, and lamp. The room was fitted with a one-way mirror. A Bio-Dyne MR-260 electromyographic biofeedback device providing con-

tinuous auditory (fluctuations in tone) feedback was used in this study. With the exception of two subjects, the sensitivity-gain adjustment was set at 25 μ V. For two subjects the sensitivity-gain adjustment was set at 10 μ V for the initial session only. Three electrodes, each with a surface area of approximately 5.65 cm², were secured with a rubber headstrap approximately 28 cm apart. The electrodes were centered and placed horizontally on the subject's forehead. The frontalis surface area was prepared with isopropyl alcohol. Cor-Gel electrocardiogram electrode gel was used as the contact medium.

Measures

The advanced level of the Otis-Lennon Mental Ability Test (Otis & Lennon, 1967) was used as a pre-post performance measure. This instrument has been found to exhibit strong test-retest reliability ($r = .94$) over a 1-year period (Smith, 1970). Split-half, Kuder-Richardson, and alternate-forms reliability coefficients also have been found to range from .92 to .96 (Otis & Lennon, 1967). The Otis-Lennon was administered using directions modified to increase subject anxiety. More specifically, these instructions stated that subjects would be rank ordered in terms of the test results and would be provided with their individual standing in comparison to other students. Following the Otis-Lennon, the State-Trait Anxiety Inventory (STAI; Spielberger, Gorsuch, & Lushene, 1970) was administered. At posttesting these same two measures were readministered along with the TAS (Sarason, 1957).

Procedure

Subjects in the two treatment and attention-placebo conditions each received six 45-minute individual sessions over a period of 2 weeks. Pretesting and post-testing occurred within 3 days of initiating and terminating treatment, respectively. All subjects for these three conditions were seated in a reclining chair and received relaxation instructions from a cassette tape recording. In preparing the tapes, the narrator was unaware of the hypotheses, measures, or rationale for the study.

EMG-assisted cue-controlled relaxation group (CCR-B). After the subject was seated by the experimenter, electrodes were attached over the frontalis muscle in accordance with the operating manual. The sensitivity-gain scale was set at 25 μ V, and the subject was asked to relax comfortably with eyes closed for approximately 30 sec to establish a baseline of audible feedback. Periodic observations were made during the session through the one-way mirror to insure that continuous feedback was being generated. Once feedback was established, the experimenter began the tape recording and left the room. The tape included three components: (a) a brief statement of rationale for EMG biofeedback training, (b) instructions for progressive relaxation training prepared from Bernstein and Borkovec (1973), and (c) instructions for cue-controlled relaxation

training as presented by Russell and Sipich (1973). More specifically, instructions for the third component directed the subject to focus on his or her breathing and to say the word *relax* with each exhalation. This was continued for approximately 20 pairings. After a 60-sec interval during which the subject was instructed to focus his or her attention on general feelings of relaxation, 20 additional pairings were rehearsed prior to terminating the session. For both cue-controlled relaxation groups, the subject was instructed to use this relaxation technique when faced with daily anxiety-evoking situations, including academic tests.

Cue-controlled relaxation group (CCR). Subjects in this condition were treated in the same manner as subjects in the preceding condition, with the exception that no biofeedback apparatus was used. The tape for this condition was identical to that for the biofeedback group, except that the first component presented a brief rationale for the use of relaxation training only, and all references to biofeedback were deleted.

Attention-placebo group (AP). Subjects in this condition were treated in the same manner as subjects in the CCR group. The tape for this condition, however, consisted primarily of soothing music performed by Roger Williams. A brief rationale for the use of music for relaxation purposes was presented, and at four points during the music the narrator used suggested imagery unrelated to test taking. There were no references during this tape to either biofeedback or cue-controlled relaxation. The AP tape was approximately 37 minutes in length, as compared to 42 minutes for the two other treatment tapes. All three tapes included statements encouraging the subjects to practice their respective treatments daily at home and to use their respective strategies in anxiety-evoking situations. After the initial session, the rationale component of each of the three tapes was deleted for the remaining five sessions.

No-treatment control group (NT). Subjects in this group were told that due to facility limitations, treatment could not be provided at present and that they had been placed on a waiting list for treatment in the future.

Statistical Analysis

Statistical analysis was conducted using gain scores (Huck & McLean, 1975) on the TAS, the STAI State scale (A-State), the STAI Trait scale (A-Trait) and the Otis-Lennon Mental Ability Test. For these dependent variables, two a priori orthogonal comparisons were conducted using t tests. The comparisons included the two treatment conditions combined versus the two control conditions combined and the CCR-B condition versus the CCR condition.

To test for main effects, the dependent measure gain scores were subjected to a series of univariate analyses of variance. Post hoc comparisons, using Scheffé's multiple range test, were conducted for those dependent variables yielding a significant F ratio. The level of significance was set at .05 in all cases.

Note. CCR-B = electromyographic-assisted cue-controlled relaxation; CCR = cue-controlled relaxation; AP = attention placebo; NT = no treatment; TAS = Test Anxiety Scale; A-State = State scale of the State-Trait Anxiety Inventory; A-Trait = Trait scale of the State-Trait Anxiety Inventory; Otis-Lennon = Otis-Lennon Mental Ability Test.

Results

Analysis of variance of pretest scores yielded nonsignificant *F* ratios across all dependent variables. Pretest and posttest group means and standard deviations for the dependent variables are presented in Table 1.

Self-report measures of test anxiety and state anxiety indicated that the combined experimental conditions were superior to the combined placebo and no-treatment control conditions. No differences were noted for the self-report measure of trait anxiety. Results

from the Otis-Lennon indicated that the combined treatment conditions made gains on this performance measure that were significantly greater than the combined control conditions. There were no differences, however, between EMG-assisted and traditional cue-controlled relaxation training in terms of any of the dependent measures. The *t* ratios for these *a priori* comparisons are presented in Table 2.

The series of univariate analyses of variance of change scores yielded significant *F* ratios for three dependent variables as follows: TAS, $F(3, 36) = 4.388$, $p < .01$; A-State,

Table 2
A Priori Orthogonal Comparison t Values for the Four Dependent Variables

** $p < .01$.

*** $p < .001$.

Table 3

Means, Standard Deviations, and Post Hoc Comparisons for the Change Scores of the Four Dependent Variables

Variable	Treatment condition							
	CCR-B		CCR		AP		NT	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
TAS	-4.0 _{a,b}	5.59	-7.9 _a	5.85	-4.1 _b	4.14	-.3 _b	2.21
A-State	-18.8 _a	12.76	-20.9 _a	14.21	-16.1 _a	8.60	-1.9 _b	4.33
A-Trait	-5.3 _a	4.47	-7.7 _a	6.71	-7.6 _a	6.27	-3.8 _a	4.04
Otis-Lennon	8.0 _a	5.14	8.1 _a	3.24	2.4 _b	3.71	2.4 _b	2.91

Note. Scheffé's multiple comparison test is at the .05 level. Means with the same subscript are not significantly different. CCR-B = electromyographic-assisted cue-controlled relaxation; CCR = cue-controlled relaxation; AP = attention placebo; NT = no treatment; TAS = Test Anxiety Scale; A-State = State scale of the State-Trait Anxiety Inventory; A-Trait = Trait scale of the State-Trait Anxiety Inventory; Otis-Lennon = Otis-Lennon Mental Ability Test.

$F(3, 36) = 6.429$, $p < .01$; and Otis-Lennon, $F(3, 36) = 7.178$, $p < .001$. Post hoc comparisons using Scheffé's test for multiple comparisons indicated that the CCR condition was superior to the no-treatment condition but was no different from the CCR-B or AP conditions for the TAS. In terms of state anxiety the CCR, CCR-B, and AP conditions were found superior to the no-treatment condition. No differences were found between conditions for trait anxiety. Both the CCR and CCR-B groups were found to result in significantly greater gains on the Otis-Lennon when compared to either control condition, but they were not significantly different from each other. Without exception, subjects in the experimental conditions increased performance at posttesting. These increases ranged from 2 to 18 points. For the two control conditions, however, these gains were found to range from 1 to 8 points only. Furthermore, 30% of the subjects in the control conditions actually demonstrated a decrease in performance at posttesting. Means and standard deviations for the change scores for the four dependent variables by treatment condition are presented in Table 3.

Discussion

As hypothesized, the combined cue-controlled relaxation conditions were found to reduce self-reported test anxiety and state

anxiety more than the placebo and no-treatment conditions. Also, the combined experimental conditions resulted in a greater increase in test-taking performance than the combined control conditions. However, the hypothesis that EMG-assisted cue-controlled relaxation would be superior to traditional cue-controlled relaxation was not supported.

The findings indicate that these approaches to cue-controlled relaxation may be effective for the treatment of test anxiety. However, despite the considerable enthusiasm generated around the use of EMG biofeedback in relaxation training, it appears to add little to the effectiveness of cue-controlled relaxation. The general assumption that frontalis relaxation via EMG training generalizes to other muscle groups may not be totally accurate. Alexander (1975) found little evidence to support the use of EMG biofeedback alone in inducing generalized muscular relaxation. Given the potential cost and inconvenience of using EMG training, it may not be the treatment of choice for approaches using generalized relaxation training. The area in which biofeedback is making its most important contribution appears to be in the field of specific psychophysiological disorders (Budzynski, Stoyva, & Adler, 1970; Budzynski, Stoyva, Adler, & Mullaney, 1973).

Of particular interest in this study is the significant increase in test-taking performance for the subjects in the experimental conditions. The mean gains on the Otis-Lennon for these

subjects translated into an increase of between 7 and 24 IQ points, depending on the location of the scores in the distribution. The mean gain scores for the combined control conditions translated into an increase of between 1 to 4 IQ points only. The literature dealing with the modification of test anxiety is replete with research yielding significant differences in self-reported test anxiety. Increases on performance measures, however, are not as plentiful. Finger and Galassi (1977) stated that a review of the literature revealed that performance improvements were obtained in only 16 (29.6%) of 54 studies. Although the present study resulted in significant increases in scores on a test of mental ability, replication and further investigation using performance measures is needed.

It is noteworthy that we found no differences in the reduction of anxiety between the experimental treatments and the attention-placebo condition on any self-report measure. This would emphasize further the need for performance as well as self-report measures in the assessment of test anxiety.

There are several important questions that remain unanswered. For one, what are the differential treatment effects for individual subjects receiving EMG-assisted cue-controlled relaxation? It may be that subjects who are trained successfully to modify EMG frontalis responses will demonstrate an increase in performance, whereas those who fail to do so will not. Research designed to answer this question is needed.

Implications for further research with cue-controlled relaxation itself include investigating the relative contributions of various approaches to relaxation training and various forms of the subvocalized cue words. The possible inclusion of additional subvocalized statements as a supplement to the cue word appears promising. In this manner, many of the task-orienting self-verbalizations recommended by Meichenbaum (1977) could be incorporated into the cue-controlled relaxation treatment. Cognitive behavior modification approaches, without relaxation, could also be compared to cue-controlled relaxation. In this manner the relative importance of relaxation training in the treatment of test anxiety could be assessed.

Vicarious Anxiety: A Systematic Evaluation of a Vicarious Threat to Self-Esteem

Philip C. Kendall

This research investigated, in three studies, subjects' state anxiety arousal in response to an in vivo vicarious threat to self-esteem. In Studies 1 and 2 students observed a guest speaker who provided the anxiety manipulation. In both studies, correlation and median split analyses indicated that high empathic and low trait anxious subjects reported elevated state anxiety in response to the vicarious threat. Even though external subjects reported overall higher levels of state anxiety, no differential responsiveness between internal and external subjects was found. When subjects were *matched* on initial state anxiety, high-empathy subjects were found to have experienced vicarious anxiety, whereas subjects low on empathy did not. An analysis of high and low trait anxious subjects who were matched on initial state anxiety did not reveal differential responsiveness. In addition to replicating Study 1, Study 2 found that the *Helplessness: an inability to affect change in others* factor of locus of control was significantly negatively related to empathy, and the cognitive reappraisal styles of reversal (denial, reaction formation) and projection were related to state anxiety *decreases*. Study 3 provided evidence for the absence of a confound.

Imagine an evening "on the town" in which an audience is exposed to a theatrical misfortune—an unprepared understudy. As anyone who has been in such a situation knows, there will be large differences in the behavior of the ticket holders. Some will demand a refund, whereas others will feel sorry and work themselves into an anxious sweat! What are the relevant personality characteristics and cognitive reappraisal styles that are associated with such response variation?

Present psychological evidence tends to support the notion that virtually all learning

phenomena that are directly experienced can also occur vicariously through the observation of another person (Bandura, 1969). The majority of the evidence demonstrates that such observation affords the acquisition of response patterns and the therapeutic benefits of a coping model. In the present study observational or vicarious emotionality (anxiety), a less desirable response pattern, was investigated.

Those investigations that have in the past targeted emotionality have usually been concerned with such variables as the type of stress (physical danger threat or threat to self-esteem: Bennett & Holmes, 1975; Kendall, 1978; Kendall, Finch, Auerbach, Hooke, & Mikulka, 1976; Speisman, Lazarus, Mordkoff, & Davison, 1964) and the nature of the stress experience (direct or vicarious: Alfert, 1966, 1967; Averill, Olbrich, & Lazarus, 1972; Opton & Lazarus, 1967), whereas others have in-

Portions of the present article were prepared while the first author was at the Center for Advanced Study in the Behavioral Sciences, Stanford, California. This research was initiated while the first author was affiliated with Virginia Commonwealth University.

cluded an examination of threat reduction via defensive styles (Bennett & Holmes, 1975; Holmes & Houston, 1974; Lazarus, Opton, Nomikos, & Rankin, 1965; Speisman et al., 1964). Uniformly, these studies have been conducted in the laboratory setting.

When one organizes the studies in this area and examines a matrix of stress type (physical, ego threat) and nature of stress (vicarious, direct) variables, there is an absence of an evaluation of observational ego threat or vicarious stress to self-esteem. The intent of the present investigation was to conduct such a study and to examine the characteristics of subjects who would experience vicarious anxiety. Three personality measures were selected: empathy (Hogan, 1969), locus of control (Nowicki & Duke, 1974), and anxiety (Spielberger, Gorsuch, & Lushene, 1970).

It was hypothesized that subjects scoring high on empathy, indicating a high degree of sensitivity to the feelings and needs of others, would respond with increases in their personal state anxiety greater than those of the low-empathic subjects following a vicarious threat to self-esteem. Regarding locus of control (i.e., internal control reflecting a generalized expectancy that outcomes or reinforcement are a consequence of one's own behavior, and external control suggesting an expectancy that outcomes are the result of luck, fate, chance, or powerful others), the empirical findings (see Phares, 1973) support the notion that externals are more anxious than internals (Ray & Katahn, 1968; Watson, 1967), and, correspondingly, it was hypothesized that external subjects would be more likely to respond with vicariously aroused state anxiety than internal subjects. Finally, in line with the state-trait theory of anxiety (Spielberger, 1972), which posits that high trait anxious subjects are more prone to experience elevated states of anxiety, it was predicted that high trait anxious subjects would respond with greater state anxiety than low trait anxious individuals to the vicarious threat to self-esteem.

To reduce the unwanted variability due to expectancy and role playing, an *in vivo* situation was selected. Thus, the present study set out to directly and intentionally evaluate subjects reporting state anxiety reactions in a

naturally occurring stimulus condition that includes a vicarious threat to self-esteem.

Study 1

Method

Subjects

The subjects in this study were 30 undergraduate psychology students enrolled in an evening introductory class at an urban Virginia university. There were 14 males and 16 females, with a mean age of 24.5.

Measures

Empathy. Hogan's (1969) empathy scale is a 64-item inventory that requires subjects to endorse true or false items as they apply and measures an individual's sensitivity to the needs of others.

Locus of control. The Adult Nowicki-Strickland Internal-External Scale (ANSIE; Nowicki & Duke, 1974) is a 40-item true-false inventory that assesses an individual's belief in personal control over reinforcements (internal) or that luck, fate, chance, or powerful others are the source of reward (external).

Anxiety. The State-Trait Anxiety Inventory (STAI; Spielberger et al., 1970) consists of two separate 20-item self-report scales for measuring state anxiety (A-State) and trait anxiety (A-Trait). The STAI A-State scale requires people to describe how they feel at a particular moment in time; the STAI A-Trait scale asks people to describe how they generally feel. The A-State scale assesses anxiety at the moment in a given situation, whereas the A-Trait scale measures an individual's global predisposition to feel anxious.

Procedure

Subjects were distributed the empathy and locus of control scales and were required to complete and return them to their instructor. The STAI was administered according to standard instructions during a lecture period under nonstress conditions. Subjects were merely informed that the instructor was "collecting some research data and needed for everyone to fill them out." They were also informed that their scores would not be individually analyzed but that the information would be grouped together for comparisons.

During a later lecture period, the subjects were informed that there would be a guest speaker¹ who would talk on "child psychopathology" and that the speaker was a recognized professional who had published numerous articles in the area. In fact, the guest speaker was a confederate who would perform the experimental manipulation. The manipulation consisted of an introduction by the instructor and a general

¹ The guest speaker was in fact a recognized clinical child psychologist who participated as a confederate and who had prerehearsed the anxiety manipulation.

statement by the guest speaker stating the topic of his talk and that the class would be asked to fill out a questionnaire used in related research as a demonstration. Then a series of events followed, including brief and intermittent stuttering, repeating phrases, mixing ideas, spilling coffee, dropping papers, misplacing slides, and an undelivered slide projector. The series of events lasted between 6 and 7 minutes. When the slide projector could not be located, the confederate guest speaker suggested that the class fill out the demonstration questionnaire while he and the instructor would try to get the slides and projector organized. The STAI was distributed, and subjects were instructed to read the instructions and complete the inventory.

Debriefing

When all subjects had completed the STAI, the manipulation was explained. The guest speaker then presented his talk normally while the instructor and an assistant examined the data. At the end of the guest talk, a brief summary of the results of the present experiment was discussed with the class.²

Results

The change in subjects' A-State from the initial nonstress phase to the postmanipulation phase was examined in a series of analyses for each of the personality measures. In each case, the correlations of the personality measure with the initial nonstress A-State score and the A-State increase score (postmanipulation A-State minus initial A-State) are presented. The correlations are followed by separate 2 (personality variable: median split) \times 2 (trials: premanipulation and postmanipulation) analyses of variance. In addition, when sufficient subjects could be included, subjects *matched* on their initial A-State scores were subjected to 2 \times 2 analyses of variance³ similar to those conducted on all subjects using the median split.

Empathy

The correlation between empathy scores and the initial A-State scores was $-.26$, which only approached significance. However, empathy was significantly correlated with an increase in A-State scores ($r = .39$, $p < .05$). This significant correlation indicates that empathy is directly related to reported elevations in A-State.

When subjects were divided at the median

Figure 1. Mean State-Trait Anxiety Inventory State Anxiety (STAI A-State) scores for high- and low-empathy subjects at premanipulation and postmanipulation. (The left portion includes all subjects divided at the median; the right portion includes certain subjects matched on initial A-State scores.)

(38) into high-empathy (>38) and low-empathy (<38) groups (both $n_s = 13$; 4 subjects whose scores equaled 38 were eliminated), the analysis of variance indicated nonsignificant main effects for empathy level and trials, $F_s(1, 24) < 1$. The Trials \times Empathy interaction was significant, $F(1, 24) = 14.27$, $p < .005$, indicating that the A-State scores of high-empathic subjects increased due to the manipulation, whereas the A-State scores of the low-empathic subjects decreased (see lefthand portion of Figure 1). The means of the A-State scores for subjects high and low on empathy were pre = 37.0 and 43.69 and post = 42.46 and 35.15, respectively. As shown in Figure 1, high-empathy subjects were at higher A-State levels following the manipulation than they were at the premanipulation phase. In contrast, low-empathy

² Although several students reported feeling very badly for the guest speaker (one cleaned up the coffee during the talk), the class unanimously stated that they were unaware that it was a manipulation. Importantly, the class also volunteered that the debriefing which included an explanation of some of the results of the study was a very stimulating and innovative teaching method.

³ Subjects' scores were considered matched within a 1-point range. A matched group analysis of variance was not used.

subjects were less anxious following the manipulation. Thus, subjects who scored high on empathy were those who reported a vicarious anxiety response.

However, a reevaluation of the left-hand portion of Figure 1 reveals that the initial A-State scores for the two groups differ substantially. (Recall also the $-.26$ correlation between empathy and initial A-State.) Anxiety is not entirely independent of empathy, and legitimate inferences about the effect of empathy on state anxiety can be drawn only when empathy is varied independently of anxiety.⁴ To achieve independence, 16 subjects from the high- and low-empathy groups were matched according to their initial A-State scores, and changes in anxiety were analyzed. The premanipulation and postmanipulation means for the matched high- and low-empathy groups were pre = 36.75 and 37.25 and post = 43.25 and 33.37, respectively. Results of a 2 (empathy level) \times 2 (trials) analysis of variance indicated nonsignificant main effects for empathy level and for trials, $F_s(1, 14) < 1$, but a significant interaction, $F(1, 14) = 10.91$, $p < .001$. This finding is presented in the right-hand portion of Figure 1. Here, the high-empathy subjects reported increased levels of state anxiety following the manipulation, and the low-empathy subjects reported decreased anxiety. The results of the matched-subjects analysis coincide with those reported for the median-split procedure and demonstrate more clearly the effects of empathy on A-State changes.

Locus of Control

The correlation between locus of control and the initial A-State score was $.39(p < .05)$, and the correlation between locus of control and the increase in A-State scores was $.09(p > .10)$. These findings support those of Ray and Katahn (1968) and Watson (1967), who reported that external subjects score higher on anxiety than internals. However, the present evidence does not support the hypothesis that externals would be more likely to experience vicarious anxiety.

When subjects were divided at the median (9) into internal ($n = 11$, scores < 9) and external ($n = 9$, scores > 9) locus of control

groups (10 subjects whose scores were 9 were eliminated), the results of a 2 (internal/external) \times 2 (trials) analysis of variance indicated a significant main effect of locus of control, $F(1, 18) = 11.61$, $p < .005$, a nonsignificant main effect for trials, $F(1, 18) = 1.04$, and a nonsignificant interaction, $F(1, 18) = 1.59$. Examination of the means for the internals and externals (pre = 35.09 and 44.22 and post = 29.27 and 46.22, respectively) indicated that the significant internal/external difference in A-State was reflected in the higher A-State scores for externals. An attempt to analyze for the effects of locus of control on state anxiety with subjects matched on initial A-State was aborted by the limited number (i.e., three) of matched cases.

Anxiety

The correlation between A-Trait and the initial nonstress A-State was $.59(p < .01)$, and the correlation between increases in A-State and A-Trait scores was $-.48(p < .01)$. The significant A-Trait/A-State correlation is not surprising; however, the significant negative correlation of A-State increases and A-Trait scores was not expected. This unexpected finding suggests that it was the lower A-Trait scores that were related to the greater state anxiety increases.

When subjects were divided at the median of their A-Trait scores (38), high A-Trait subjects ($n = 12$) had scores greater than 38, whereas low A-Trait subjects ($n = 12$) had scores less than 38 (6 subjects were eliminated by the median split). The mean A-State scores for high and low A-Trait groups were pre = 45.83 and 31.50 and post = 38.83 and 34.25, respectively. Results of a 2 (A-Trait level) \times 2 (trials) analysis of variance indicated a significant A-Trait level effect, $F(1, 22) = 13.38$, $p < .005$, and a nonsignificant trials effect, $F(1, 22) = 1.04$. The A-Trait Level \times Trials interaction was significant, $F(1, 22) = 5.49$, $p < .05$, indicating differential changes in A-State for subjects differing in A-Trait (see Figure 2). Figure 2 indicates that the low A-Trait subjects were more state anxious

⁴ The authors wish to thank an anonymous reviewer for stressing this important issue.

following the vicarious threat to self-esteem than prior to it, whereas the high A-Trait subjects reported less A-State following the manipulation. It should be noted here that the extreme scores at the premanipulation phase set limits on the probable size and direction of any change, and an analysis of subjects *matched* on initial A-State would be more desirable. Given that A-Trait and A-State are not independent, it was not surprising that only 3 subjects could be matched, and thus no matched-subjects analysis was conducted.

Discussion

The results of the present study provide strong support for the hypothesis that high-empathic subjects will respond anxiously after observing an anxious speaker. Correspondingly, the present study provides validation for Hogan's (1969) empathy scale. In a discriminant fashion, the locus of control results are also valuable. That is, locus of control appears to be unrelated to vicarious emotionality. However, external subjects did report more anxiety, as has been found in other studies.

The results of the trait anxiety analysis were not entirely as expected. Although the significant interaction of high/low trait level and trials was predicted, the finding that the low A-Trait subjects increased while high A-Trait subjects decreased in state anxiety as a function of the manipulation was *contradictory* to our hypothesis. Indeed, this is the first known study to disclose a situation in which the low A-Trait individuals were more disposed to be state anxious, and the findings are directly contradictory to those of numerous studies using different stresses (e.g., Auerbach, 1973; Hodges & Spielberger, 1966) and to the definition of A-Trait itself. A finding as surprising as this appeared to warrant replication.

Yet another potential need for replication concerns the multidimensionality of locus of control. Recent evidence using the Rotter scale (Abramowitz, 1973; Levenson, 1973) and the Nowicki-Strickland children's form (Kendall, Finch, & Mahoney, 1976) have shown that although overall locus of control is predictive, factor-specific scoring of the dimen-

Figure 2. Mean State-Trait Anxiety Inventory State Anxiety (STAI A-State) scores for all high and low Trait Anxiety (A-Trait) subjects at premanipulation and postmanipulation.

sions of locus of control can advance accurate hypotheses. The factor analytic demonstration of the multidimensionality of the ANSIE (Kendall, Finch, & Mikulka, Note 1) produced five meaningful factors. Among the factors were two representing helplessness—one that appeared to be related to an absence of alternatives or solutions and another that is suggestive of an inability to affect change in others. Another factor expressed superstitious beliefs. It was felt that perhaps, even though overall locus of control was not related to vicarious anxiety, the specific factors might be related. Specifically, the *Helplessness: An inability to affect change in others* factor of the ANSIE was hypothesized to be negatively related to the vicarious anxiety experience. In the present study, subjects watched an individual anxiously blunder through a professional presentation. Those who were sensitive to the needs and feelings of others (i.e., high on empathy) showed anxiety arousal. Similarly, it might be hypothesized that individuals who perceive themselves as being capable of affecting change in others might also be aroused.

Finally, an examination of the means of the high- and low-empathy and high and low A-Trait subjects revealed that although high-empathic and low A-Trait subjects reported increased state anxiety, the mean scores of both the low-empathic and high A-Trait subjects *decreased* after the manipulation. This

Figure 3. Mean State-Trait Anxiety Inventory State Anxiety (STAI A-State) scores for high- and low-empathy subjects at premanipulation and postmanipulation. (The left portion contains all subjects divided at the median; the right portion includes certain subjects matched on initial A-State scores.)

decrease suggests that perhaps certain cognitive reappraisals (Lazarus, 1966) had been used by these subjects and that these cognitive styles (i.e., defense mechanisms) should be examined. For this, and the above reasons, a replication and extension was conducted.

Study 2

Method

The subjects in this study were 40 undergraduate psychology students enrolled in an early morning introductory psychology class at an urban Virginia university. There were 20 males and 20 females with a mean age of 19.7.

Measures

In addition to the measures used to replicate the initial study, the Defense Mechanisms Inventory (DMI, Gleser & Ihilevich, 1969) was administered. The DMI assesses the relative intensity of five major groups of defenses. The inventory consists of 10 brief stories followed by four questions regarding the individual's actual behavior, fantasy behavior, thoughts, and feelings in the situation described. The five defense groups are (a) hostility-out (i.e., displacement), (b) projection, (c) principalization (i.e., intellectualization, rationalization, isolation), (d) turning-against-self, and (e) reversal (i.e., negation, denial, reaction formation). Validity data are provided in Gleser and Ihilevich (1969) and Gleser and Sacks (1973).

Procedure

The same experimental procedure was followed as in Study 1. Similarly, subjects were debriefed and were presented with a brief outline of the results.

Results and Discussion

As in Study 1, the A-State reaction of subjects to the vicarious anxiety manipulation was examined in a series of analyses (i.e., correlational, median-split analysis of variance, and analysis of subjects matched on initial A-State) for each of the personality measures.

Empathy

The correlation between empathy and the initial nonstress measure of A-State was $-.28$, which approached but did not reach significance. However, empathy was significantly related to A-State increases ($r = .35$). As in Study 1, the more empathic subjects reported elevated state anxiety in response to the vicarious anxiety manipulation.

When subjects were again split at the median (38) into high-empathy (>38 , $n = 20$) and low-empathy (<38 , $n = 20$) groups, the results of the analysis of variance indicated nonsignificant main effects for high/low empathy and trials, $F(1, 38) < 1$, and $F(1, 38) < 1$, respectively. The interaction of empathy and trials was significant, $F(1, 38) = 5.29$, $p < .03$, indicating that the state anxiety level of subjects high on empathy changed differentially from that of subjects low on empathy. Again, as in Study 1, high-empathic subjects showed an increase in A-State due to the manipulation, whereas the subjects low on empathy did not. This interaction is presented in the left-hand portion of Figure 3. In addition, the extent of the replication of Study 1 should be noted. (See left-hand portion of Figure 1.)

To examine the effects of empathy on state anxiety when empathy is varied independently of anxiety, 24 subjects from the high- and low-empathy groups were matched according to their initial A-State scores. The premanipulation and postmanipulation means for the matched high- and low-empathy groups were, respectively, pre = 36.72 and 36.72 and post = 46.1 and 36.40. Results indicated nonsignificant main effects, $F(1, 22) = 1.69$, and

$F(1, 22) = 1.48$, respectively, and a significant Empathy Level \times Trials interaction, $F(1, 22) = 4.37$, $p < .05$. This finding is presented in the right-hand portion of Figure 3. As can be seen, when high- and low-empathy subjects are matched on initial A-State, it is the high-empathic individuals who report experiencing vicariously aroused anxiety. It should be noted that this finding is quite similar to that found in the matched-subjects analysis in Study 1 (compare to right-hand portion of Figure 1), with the exception that the low-empathic subjects in Study 2 did not show a marked reduction in anxiety. Nevertheless, the results regarding empathy in Figures 1 and 3 represent quite similar findings. Indeed, the results of the present study provide strong, replicated support for the finding that high-empathic individuals experience vicarious anxiety arousal, whereas less empathic people do not. Moreover, the aroused anxiety due to a vicarious threat to self-esteem in the high-empathic subjects also provided validation for the empathy scale (Hogan, 1969). The state anxiety increases reported by high-empathic subjects are considered the result of their placing themselves in the position of the speaker—"If I were up there, I would be extremely anxious" or "I can imagine what he feels like." It would be interesting to examine in future research the self-statements made by empathic and nonempathic observers and their ensuing emotional response patterns.

Locus of Control

Two types of analyses were conducted using the locus of control data: analyses of overall locus of control scores and analyses of the separate factors within the locus of control scale.

Overall score analyses. The correlation between locus of control and the initial nonstress measure of A-State was .31 ($p < .05$), whereas the relationship to A-State increases was nonsignificant ($r = -.15$). As in Study 1, externals reported higher A-State, but locus of control remained unrelated to the vicarious arousal of anxiety.

Subjects were divided at the median of the overall scores (9) into internal ($n = 18$, scores < 9) and external ($n = 18$, scores > 9) groups

(4 subjects who scored 9 were eliminated) with subsequent analyses of A-State scores across trials. Results indicated nonsignificant main effects and a nonsignificant interaction, $F(1, 34) = 3.40$, and $F(1, 34) < 1$, $F(1, 34) = 1.47$, respectively. The means for the internal and external subjects, respectively, were pre = 35.16 and 43.16 and post = 38.33 and 39.27. The locus of control main effect approached significance ($p < .07$) in the direction similar to Study 1 in which externals reported more state anxiety.

To examine the effects of locus of control on A-State when locus of control is varied independently of anxiety, 22 subjects from the internal and external groups were matched on initial A-State. The premanipulation and postmanipulation means for matched internal and external subjects, respectively, were pre = 35.54 and 35.90 and post = 37.45 and 38.09. The results of the analysis of variance produced nonsignificant main effects for locus of control and trials and a nonsignificant interaction, $F(1, 20) = 1.76$, $F(1, 20) = 1.96$, and $F(1, 20) < 1$, in that order. More conclusively, these findings demonstrate that locus of control is not related to vicarious anxiety arousal.

Factor-specific analyses. Examination of the scores on the specific factors of locus of control revealed no additional meaningful relationships. That is, neither the overall locus of control score nor the five factor-specific scores were correlated with an increase in state anxiety (all r s $< .27$). Thus, the factor scores did not provide additional specificity.

On the other hand, although the overall locus of control score did not correlate significantly with the empathy measure ($r = .19$), Factor II, *Helplessness: an inability to affect change in others*, did correlate meaningfully ($-.35$, $p < .05$). This relationship suggests that subjects who are empathic perceive themselves as having the ability to affect change in others.

Anxiety

Trait anxiety correlated .61 ($p < .005$) with initial A-State and $-.52$ ($p < .005$) with increases in A-State. These results support those of Study 1 and, specifically, support the

Figure 4. Mean State-Trait Anxiety Inventory State Anxiety (STAI A-State) scores for high and low Trait Anxiety (A-Trait) subjects at premanipulation and postmanipulation. (The left portion contains all subjects divided at the median; the right portion includes certain subjects matched on initial A-State scores.)

surprising finding that it was the lower A-Trait subjects who responded with increases in A-State.

A 2 (A-Trait level) \times 2 (trials) analysis of variance of subjects divided at the median of their A-Trait scores (38) into high ($n = 20$, A-Trait > 38) and low ($n = 20$, A-Trait < 38) A-Trait groups revealed a significant main effect for A-Trait level, $F(1, 38) = 6.01$, $p < .02$, a nonsignificant main effect for trials, $F(1, 38) < 1$, and a significant interaction, $F(1, 38) = 7.75$, $p < .005$. The means for high and low A-Trait subjects were pre = 45.83 and 31.50 and post = 38.83 and 34.25. Again, similar to Study 1, the significant Trait Anxiety Level \times Trials interaction was examined and was found to indicate that the low A-Trait subjects had reported more state anxiety following the manipulation than at a nonstress period, whereas the high A-Trait subjects had reported less. This interaction is presented in the left-hand portion of Figure 4. It should be noted again that the initial A-State means were very different for the A-Trait groups and that these initial score differences set limits on the possible size and direction of change.

A more crucial examination of the effects of trait anxiety on state anxiety was conducted using 20 subjects matched on initial A-State. The premanipulation and postmanipulation means were high A-Trait = 36.9 and 33.2 and

low A-Trait = 36.5 and 33.6. An analysis of variance revealed nonsignificant differences, $F(1, 18) < 1$, $F(1, 18) = 1.29$, and $F(1, 18) < 1$, for A-Trait level, trials, and the interaction, in that order. Thus, the replicated finding in Studies 1 and 2 that high and low A-Trait subjects responded differently to the vicarious threat to self-esteem was not supported by the analysis of matched subjects. (See right-hand portion of Figure 4.)

Future research should consider situation-specific anxiety traits (Endler & Okada, 1975; Zuckerman, 1977) and the prediction of arousal based on the congruence of the class of the anxiety trait measure and that of the experimental situation (Kendall, 1978). Predictions based on the interactional assessment of trait anxiety should be quite heuristic in relation to vicarious anxiety.

Age and Sex

An examination of the correlations between age, sex, and the increase in state anxiety indicated that neither age ($r = -.25$) nor sex ($r = -.14$) were significantly related to A-State increases. In addition, neither sex nor age was related to empathy (both r s $< .08$), nor was sex related to trait anxiety ($r = .06$). Age was related to trait anxiety ($r = .33$, $p < .05$).

Cognitive Reappraisals/Defense Mechanisms

To examine the reappraisal styles of subjects who did not become anxious following our manipulation (some subjects actually de-

Table 1
Correlations of the Defense Mechanism Inventory Categories With Decreases in State Anxiety and With Locus of Control

Category	A-State decrease	Locus of control
Hostility-out	.25	.36*
Projection	.34*	.22
Principalization	.02	-.31*
Turning-against-self	.15	.08
Reversal	.42**	-.40**

* $p < .05$.

** $p < .01$.

creased in reported state anxiety), the five scores on the DMI were intercorrelated with decreases in state anxiety (initial A-State minus postmanipulation A-State). The results are presented in Table 1. As can be seen, there exist significant relationships between subjects who characteristically use reversal and projection and their changes in state anxiety. These relationships suggest that subjects who characteristically use reversal-type defenses (i.e., denial, negation, reaction formation) and projection are likely to report a nonanxious behavior pattern when exposed to an anxious model. Here, an observer using a reversing reappraisal style (e.g., denial) might think, "He's not really anxious" or an observer might project the emotionality onto another person—"It looks like the teacher is getting uncomfortable." Future research should examine the content of the self-statements made during cognitive reappraisals of threat.

Although four of the DMI categories did not correlate significantly with trait anxiety, there was a significant relationship between reversal and trait anxiety ($r = .51, p < .005$), suggesting that the high A-Trait subjects tended to rely on the reversal defensive styles. None of the defensive styles correlated with empathy.

Locus of control and defense mechanisms. Although this is an ancillary section of the present study, several findings are noteworthy. The correlations of interest were included in Table 1. As can be seen, a significant relationship between locus of control and the defense styles of reversal, hostility-out, and principalization was found. These relationships suggest that internal subjects are more characteristic users of reversal and principalization, whereas externals tend to rely on hostility-out (i.e., displacement).

The results of Study 2 suggest that the state anxiety of subjects whose style of cognitive reappraisal emphasizes reversal and projection was reduced by the anxious model. This is consistent with the findings of Houston (1971, 1973), Houston and Hodges (1970), and Lazarus and Alfert (1964), who reported the advantage of denial in stressful situations and the arousal-reducing qualities of denial and reaction formation (reversals). The present findings are supportive of Bennett and Holmes

(1975), who reported a reduction in arousal relating to projection, but are in contrast to Holmes and Houston (1971) and Stevens and Reitz (1970), who did not support the projection/anxiety reduction hypothesis. The reversal defensive mechanisms of the DMI include denial, reaction formation, and negation. The present findings support the relationship of such reversing as a style of cognitive reappraisal to obliterate anxiety arousal.

Comment on the Replication

The results of the first two studies provide replicated evidence that state anxiety as self-reported by high-empathic subjects increases following a vicarious threat to self-esteem manipulation. Trait anxiety was consistently related to both A-State and A-State increases, but A-Trait was not related to A-State increases when subjects were matched on initial A-State. In addition, internal and external subjects do not differ in their tendency to experience vicarious anxiety, but externality is related to higher levels of state anxiety.

The contexts of replicated findings are noteworthy, and the present replication is no exception. In fact, there were actually several differences between Study 1 and Study 2. First, one was an evening class, whereas the other was an 8:00 a.m. class. Second, the mean ages were 24.5 and 19.7 years, respectively. Finally, the first guest speaker for the subjects in Study 1 was the experimental manipulation, whereas, due to other commitments, there were two guest speakers prior to the manipulation for subjects in Study 2. Nonetheless, even with the contextual variations (notwithstanding the care taken to replicate the procedural matter), the results were consistent.

Study 3

Before attempting to draw any conclusions or implications from the results of the first two studies, it must first be asked whether the state anxiety changes were the result of our manipulation. According to Sarason (1972),

models, teachers, and experimenters provide two types of information: 1) what they do or say, and 2) how they do or say it. Both require intensive inquiry because neglect of one of these dimensions could nullify effects of the other. (p. 399)

Even though the results of the present studies are considered indicative of reliable characteristics of the vicarious emotional responder (and the replication and extension provided by Study 2 clearly support this), a methodological dilemma may have confounded the results. That is, the absence of a control group that experienced the guest speaker "in his usual form" prevented our conclusions from being clear-cut. The speaker himself and the manipulation were confounded. Our results could have been due to "the nature of our guest speaker." Analysis of changes in state anxiety from a nonstress to a post-guest-speaker period during which the guest speaker did not perform the anxiety manipulation was a needed control. The purpose of Study 3 was to examine such a control by analyzing state anxiety changes before and after the same guest speaker for subjects varying in empathy and trait anxiety.

Method

Subjects

The subjects in this study were 14 undergraduate psychology students. There were 2 males and 12 females, with a mean age of 23.2. All were students in a low-enrollment, summer-session undergraduate psychology class at an urban Virginia university.

Procedure

In this study the STAI and the empathy scale were administered to the entire class during a nonstress condition. The second administration of A-State followed a guest talk on the same topic as in Studies 1 and 2 and by the same guest speaker. In this study the speaker did not perform the anxiety manipulation.

Results and Discussion

Empathy

Empathy was found to be nonsignificantly related to both the initial A-State ($r = -.18$) and A-State increases ($r = -.08$). Even though both Study 1 and 2 found empathy to be significantly related to A-State increases, there was no such relationship in this study when the vicarious anxiety experience was not provided.

When subjects were divided at the median of Studies 1 and 2 (38) into high-empathy

(>38, $n = 9$) and low-empathy (>38, $n = 5$) groups, it was possible to match 5 subjects on their initial A-State scores. The means for the high- and low-empathy subjects that had been matched on initial A-State were pre = 34.4 and 34.4 and post = 32.2 and 33.6, respectively. The results of the analysis of variance indicated nonsignificant main effects for empathy and trials and a nonsignificant interaction, $F_s(1, 12) < 1$. These results indicate that with matched subjects⁶ there is no difference in A-State for subjects varying in empathy and that the guest speaker did not produce anxiety arousal. Thus, without the anxiety manipulation the speaker did not arouse anxiety.

Anxiety

Trait anxiety was significantly related to initial A-State scores ($r = .64$, $p < .05$) but was not significantly related to state anxiety increases ($r = .16$). As expected, unlike Studies 1 and 2 but in agreement with the empathy data from Study 3, A-Trait was not related to A-State increases.

When subjects were divided at the median (38) of their A-Trait scores into a high A-Trait (>38, $n = 7$) and low A-Trait (<38, $n = 7$) groups, the results of a 2 (A-Trait level) \times 2 (trials) analysis of variance indicated a significant main effect for A-Trait level, $F(1, 12) = 5.38$, $p < .05$, a nonsignificant main effect for trials, and a nonsignificant interaction, $F_s(1, 12) < 1$. The means for high and low A-Trait subjects were pre = 39.86 and 32.43 and post = 38.00 and 31.86. These results support previous findings of higher A-State for high A-Trait subjects. Also, these results indicate that the guest speaker (without the anxiety manipulation) did not produce elevations in state anxiety. In addition, there was no differential responsiveness for high versus low A-Trait subjects.

The results of the control study demonstrated that the observed anxiety reactions in Studies 1 and 2 were probably a function of the anxiety manipulation and not due to

⁶ Similarly nonsignificant results were obtained when the median split groups were analyzed.

any idiosyncrasies of the speaker himself. Thus, those findings reported in Study 1 and Study 2 should not be considered subject to a confound due to the speaker's style.

Illusory Correlation: A Further Exploration of Chapman's Paradigm

Richard M. Kurtz and Sol L. Garfield
Washington University

Even though the phenomenon of illusory correlation first researched by Chapman has been demonstrated in a variety of studies, relatively little has been done to show convincingly that this bias cannot be reduced or eliminated by training. The present study addresses itself to this issue. There were four groups of 15 undergraduate subjects each in this study. The first group was a replication of a study by Chapman and Chapman with an equal association of all valid Wheeler signs and invalid signs and statements of the patients' purported problem. Group 2 was a replication of Chapman's study, with valid signs presented 100% of the time and invalid signs presented 50% of the time. Group 3 provided subjects with a special pretraining against illusory correlation, with 50% presentation of valid signs; and Group 4 was a special pretraining of the subjects against illusory correlations, with 100% presentation of the valid Wheeler signs. It was predicted that Groups 3 and 4 would show the least amount of illusory correlation. This hypothesis was not confirmed. However, we replicated part of the Chapmans' findings that subjects predominantly associated the concept of anality with preconceived problems of homosexuality. A serendipitous finding was also noted in which subjects appeared to create their own illusory correlate.

Illusory correlations are reported associations between test responses and symptoms or syndromes that are based on verbal associative connections of the test-sign to the symptom rather than on valid observations. As defined by Chapman (1967), illusory correlation is

the report by observers of the correlation between two classes of events which, in reality, (a) are not correlated, or, (b) are correlated to a lesser extent than reported, or (c) are correlated in the opposite direction from that which is reported (p. 151).

Although the phenomenon of illusory correlation has been demonstrated in a variety of studies (Chapman, 1967; Chapman & Chapman, 1967, 1969; Golding & Rorer, 1972; Starr & Katkin, 1969), relatively little has been done to show that this bias cannot be

reduced or eliminated by proper training. The present study addresses itself to that issue.

The phenomenon of illusory correlation was first demonstrated by Chapman (1967) when subjects observed a random pairing between elements of two arrays of words and were then asked to report the frequency with which a word from one array was paired with a word from another array. He found the reported frequency of occurrence was biased upwards when the word pair was characterized by either strong verbal associative connections or by distinctiveness.

In a second study (Chapman & Chapman, 1967), subjects were shown randomly paired symptom statements and Draw-a-Person figures. They were then asked to report any drawing characteristic that they felt was associated with any of the symptoms. The relationships that the subjects reported tended to be similar to those that some clinicians reported from their clinical practices, and they basically seemed to rely on associative

Requests for reprints should be sent to Richard M. Kurtz, Department of Psychology, Washington University, St. Louis, Missouri, 63130.

connections between the drawing characteristics and the symptoms.

In one of the nuclear studies conducted by Chapman and Chapman (1969) on the Rorschach, they found that expert diagnosticians, on the basis of their clinical experience, and naive judges, on the basis of their observations of random materials, tended to report the same Rorschach signs as being valid indicators of homosexuality. This was found to be the case even though these signs had not been demonstrated in the previous research literature to relate to the purported problem of homosexuality, nor did they have, in the experimental task, a nonrandom association with the purported problem of homosexuality. The basic experimental task used by Chapman and Chapman was to present a series of Rorschach cards in which for each Rorschach response or percept two statements of an emotional problem allegedly given by a purported patient were paired to that particular part of the Rorschach blot. The task of the subjects in the Chapman study was to look at these paired associates of the Rorschach percept and the statement of the problem and, at the end, to indicate whether or not they noticed any kind of response that was seen most often by patients with this particular problem.

Consistent with previous studies, Chapman and Chapman (1969) found that subjects picked those percepts that had the highest verbal associative connection with the symptom, in this case homosexuality. In addition, Chapman and Chapman (1969) demonstrated that subjects still tended to report the popular invalid sign¹ disproportionately even when it was paired randomly with the symptom "homosexuality," and the unpopular valid sign was paired 100% of the time with the same symptom.

In an extensive replication, Golding and Rorer (1972) came to the same conclusion. They found in replicating Chapman and Chapman's (1969) study on illusory correlation that little change occurred even when the nonillusory (Chapmans' so-called "valid") cues were paired 100% of the time with the symptom of homosexuality and when the illusory cues (Chapmans' so-called "invalid" signs) had a randomly paired relationship

with the symptom of homosexuality. They also found that the different modes of feedback to the subjects and different symptom-base rates did not produce differential effects in posttraining estimates of the illusory correlation. From this they concluded that training (as experimentally defined) has very little effect on the illusory correlation.

The present study attempts to explore whether training can effect the illusory correlation. One of the problems inherent in the previous research is that attempts to modify the illusory correlation have only been minimally manipulated with the device of changing the amount or the percentage of time that nonillusory (the so-called valid) or the illusory signs (the so-called invalid) are paired with the purported problem of homosexuality in the experimental task. Perhaps with more explicit training, that is, warning the subjects that they must be on guard against illusory correlations, and showing them examples of such associative connections, that perhaps the subjects' tendency to fall prey to illusory correlations could be reduced.

There were four groups in the present study. The first group was a replication of a part of Chapman and Chapman's (1969) study (Experiment 2, p. 275) with an equal association, that is 50% presentation of all valid and invalid signs with all statements of the patient's purported problem. The valid signs were those designated by Chapman and Chapman (1969) based on the work of Wheeler (1949). Group 2 was a replication of a part of Chapman and Chapman's (1969) study (Experiment 3, p. 277), with valid signs presented

¹ For detail of the discussion of how Chapman and Chapman (1969) empirically developed the concept of valid and invalid signs, see their article (pp. 272-275). As the methodology was quite complex and space is limited, suffice it to say that a "valid sign" was one that they found in the literature to be empirically related to actual reported homosexuality, and "invalid signs" were ones that clinicians believed predicted homosexuality but in fact did not. The valid and invalid signs were either randomly assigned to a variety of different purported problems or were presented either 50% or 100% of the time with the actual problem of homosexuality. The present study duplicates part of their total experiment, that is, their Experiments 2 and 3.

100% of the time with the symptom of homosexuality and invalid signs presented 50% of the time with the symptom of homosexuality. Group 3 was a special pretraining of the subjects against illusory correlation with 50% presentation of valid signs, and Group 4 was a special pretraining of the subjects against illusory correlation with 100% presentation of valid signs. It was predicted that Groups 3 and 4 would show the least amount of illusory correlation. In other words, a linear trend was expected, with Group 1 showing the greatest amount of illusory correlation, then Group 2, Group 3, and Group 4 showing the least.

Method

Subjects

Four groups of 15 volunteer subjects of both sexes² each ($N=60$) were secured from undergraduate abnormal psychology classes at Washington University. The subjects were told that the authors were studying training parameters that affect Rorschach interpretation and that they needed the help of an untrained population to study basic patterns of test interpretation.

Test Instrument

The same materials used by Chapman and Chapman (1969) were used in the present study. These consisted of 30 Rorschach cards that were transferred to transparencies. On each of the transparencies, one percept or response was paired with two statements of emotional problems of a purported patient who was alleged to have given that specific response. The Rorschach percepts were indicated by circling an area of the card and pasting a typed statement of the patient's verbalization. For example, one of the 30 Rorschach responses labeled *Bugs Bunny* was given to the center area (D7) of card 5 (Beck, Beck, Levitt, & Molish, 1961). In the corner of the card appeared the statement, "The man who said this (1) had sexual feelings toward other men and (2) feels sad and depressed much of the time." The 30 percepts were chosen so that 6 fell into each of the five following categories: (a) popular invalid sign or a sign highly connected with associative material, in this case, human or animal anal content; (b) Wheeler Sign No. 7 (for more complete discussion of the Wheeler signs, see Chapman & Chapman, 1969); (c) Wheeler Sign No. 8; (d) geographical features, a filler category; and (e) food, another filler category.

The two statements of emotional problems or symptoms listed on the cards were drawn from a pool of four such statements, and these were identical to those used by Chapman and Chapman (1969).

They were (a) "he has sexual feelings toward other men"; (b) "he believes other men are plotting against him"; (c) "he feels sad and depressed much of the time"; and (d) "he has strong feelings of inferiority." The statements of symptoms (diagnostic cues) and Rorschach percepts were paired on the 30 cards so that each of the four statements appeared 15 times in Groups 1 and 3. Each symptom statement was thus paired with 3 of the 6 percepts from each of the five categories of percepts. Thus, for Groups 1 and 3 there was no intrinsic relationship between the occurrence of any one of the four symptoms and any one of the five categories of response. In Groups 2 and 4, the valid statement (both Wheeler signs) occurred 100% of the time with the purported problem of homosexuality, and the invalid statements occurred 50% of the time.

Procedure

The subjects were given some brief introductory information as to the nature of the Rorschach. However, no information was given about categories of either content or determinants. All groups received the following instructions:

I am going to give you a brief introduction to the well-known Rorschach test and then ask you to perform some exercises on it.

As many of you know, the Rorschach is a test of personality functioning. It basically consists of a set of inkblots to which the subject is asked to respond by describing what he perceived in each of the inkblots. It is believed that what the individual sees and describes will reveal important aspects of his personality. If he is concerned or fearful about certain problems or has conflicts in certain areas, these may be reflected in his responses to the Rorschach inkblots. How the individual perceives different blots or segments of the blots, as well as the content of his responses, may thus tell us some potentially important things about his personality.

This will suffice as a brief, general overview of what the test aims to appraise.

I am going to show you a series of inkblots, one at a time. On each inkblot you will find a typed statement of what one patient saw on this blot and also what his two chief emotional problems are. Each of these 30 cards represents a different patient. You will see what 30 different patients

² Chapman and Chapman, in their 1969 study, did not designate the sex of the subjects. In the present study, half of the subjects were male and half were female, and they were randomly assigned to each of the four training conditions. No further analysis was done by sex.

said they saw on a card. Now let me tell you what I want you to do. Please carefully study each ink-blot and the statement of what the patient said he saw in it. Also, study the statement of the patient's two severe emotional problems. When everyone has looked at all of the cards, I'm going to give you a questionnaire in which I will ask you about the kinds of things seen by patients with each kind of problem. [This paragraph is from Chapman and Chapman, 1969, p. 276]. Is that clear? All right, then, we'll go ahead.

Besides the above instructions Groups 3 and 4 also received these additional training instructions:

Before we proceed, however, it is worthwhile to also present a few important cautions. Sometimes interpretations are made that are not based on actual empirical findings about the test. Instead, individuals may make interpretations which are based on what *appear to be* verbal or logical similarities between the content of the response and a certain type of personality problem. Let me give you some examples of what I mean. For example, since paranoid individuals are seen as suspicious, responses which depict "eyes" or "someone staring" may be interpreted as indications of paranoid personality—even though this has not been really demonstrated. In a similar fashion, psychologists have interpreted responses depicting explosions or destruction as signifying aggression on the part of the person making such responses. In other words, these individuals are making some associational tie between the response and the interpretation—although such interpretations have not been supported by subsequent research. This is a common error in Rorschach interpretations and should be guarded against. You should be on your guard and alerted against making such obvious kinds of associations which seem to go together verbally but actually are not related. Instead, try to base your conclusions on the personality characteristics which have been found to be associated with certain kinds of responses to the ink blots in the material to be presented to you. Since this is a very important aspect, let us go over these points again. [This paragraph was then repeated.]

The cards were then circulated in a prearranged pattern so that each subject saw each of the 30 cards for 60 sec. The order of presentation was systematically counterbalanced so that none of the content categories (i.e., Wheeler 8, Wheeler 7, geography, anal, food) appeared more than once in a sequence. After the 30 cards were presented, the subjects were given the following questionnaire, which is identical to that used by Chapman and Chapman (1969, p. 276).

Some of the things in inkblots were seen by men who had the following problem:

He had sexual feelings toward other men.

Did you notice any kind of general thing that was seen most often by men with this problem?

Yes _____ No _____

If your answer is yes, name that kind of thing and give one example of that kind of thing. Kind of thing _____

Example _____

The identical format was followed for the other three diagnostic problems: "He has strong feelings of inferiority"; "he feels sad and depressed much of the time"; "he believes other people are plotting against him." After the subjects completed this questionnaire, they were asked to list any and all of the reactions and hypotheses that they formulated while participating in the experiment. Following this, they were debriefed.

Results

To test the major hypothesis that special training could affect the illusory correlation, a 4×4 repeated measures analysis of variance was performed on dichotomous data (Winer, 1962) with repeated measures on the second factor. The mean number of illusory correlates seen by Group 1 (50% presentation valid-invalid signs; no training) was 7.8; the mean for Group 2 (100 valid, 50% invalid; no training) was 8.0; for Group 3 (50% presentation valid-invalid; training) was 9.5; and the mean for Group 4 (100% presentation valid, 50% invalid; training) was 9.3.

The main effects for the training groups were insignificant, ($F < 1$; MS for treatments = .21, $df = 3$; error = .31, $df = 56$). A significant main effect for diagnostic cue was found, $F = 19.1$, MS for cue = 3.4, $df = 3$; MS error = .18, $df = 168$). The interaction was also insignificant ($F < 1$).

The mean number of illusory correlates seen for the cue of sex was 11.5; for inferiority, $M = 10.5$; for depression, $M = 3.5$, and for paranoid, $M = 9.0$, with the difference between the means of depression and the other three accounting for the significant F value.

Examining the data in the same way that Chapman and Chapman (1969) did, a chi-square was computed on the sexual variable of homosexuality and broken into four categories—(a) number of anal responses seen; (b) number of combined valid Wheeler signs seen; (c) number of filler items, that is.

Table 1
Percentage of Illusory Correlates Given by All Subjects to Diagnostic Cues

Response	Purported patient problems (diagnostic cues)			
	Inferiority	Sexual	Depression	Paranoid
Anal (invalid sign)	2	55	3	0
Wheeler (valid sign)	13	20	2	23
Geography	5	2	5	20
Food	3	0	5	3
Other	2	0	5	3
"Looks small"	45	0	3	12
No response	30	23	77	40

geography, food, other; and (d) no illusory correlation seen. Since only one response occurred in Category 3, this category was dropped and the response was placed in Category 4. The obtained frequencies for Category 1 was 33; for Category 2, 12; and for Collapsed Categories 3 and 4, 15. The expected frequencies were 20 in each category. The obtained chi-square of 12.9 ($df = 2$) was significant beyond the .005 level and was consistent with the data reported by Chapman. Thus, in this part of the study we completely replicated part of the findings of Chapman and Chapman (1969, Experiments 2 and 3).

Due to the unexpectedly high number of illusory correlates seen for the category of inferiority as well as paranoia, all data were cast into Table 1, which shows the percentage of illusory correlates for the purported problems of patients and the content of the Rorschach area. Since the initial category of "other" was composed predominantly of subjects' statements that said that the patient had problems of inferiority because the area seen by the patient was small or tiny, this category was then divided into two: "other" and "looks small." Thus, a post hoc category of "things that look small"^a was added. The remainder of the other category for problems of inferiority accounted for only 2% of the illusory correlation, whereas the new category of "seeing things as small" accounted for 45%. On the other hand, the expected anal content far outweighed that of the Wheeler signs for the problem of homosexuality. Fifty-five percent of the subjects gave the response "anal content" for what they most often saw from men with sexual

problems. None of the subjects used the category looks small in association with sexual problems. There does not appear to be any consistent pattern with the purported problem of paranoia, as 20% of the subjects used Wheeler signs, 20% used geography, and 12% used category looks small. The largest majority, 77%, saw no illusory correlates in relationship to the problem of depression.

The frequency of percepts being characterized as looks small suggests that the subjects may have invented an illusory correlate for the problem of inferiority. If this were so, it would be significant, since this concept was not linguistically built into the experimental material.

Even though the data are convincing for Chapman's position, when one examines the sex problems versus the Wheeler signs, it appears from the overall data that the phenomena of illusory correlation may be much more complex. Besides the area of content-triggered interpretations, it would appear that subjects try to find some meaning in the clinical material presented. In the case of inferiority, the subjects seem to have selected an aspect of the blot configuration associated with smallness and then associated this aspect with "inferiority feelings" that were not, in a strict sense, linguistically triggered by the

^a The category "seeing things as small" consisted of the subjects' responses to small details of the Rorschach blot (see Beck, Beck, Levitt, & Molish, 1961) and statements of "small in area," "small things," "tiny things," and so on. A response was not considered belonging to this category if any other content was indicated, that is, "small island."

content. Also, considering the high number of illusory correlates (i.e., 60%) given by subjects to the problem of paranoia, it does appear as if there is a strong tendency among subjects to find meaning in clinical material even if such meaning does not exist.

Discussion

In spite of the fact that attempts were made to influence the illusory correlation by providing a simulated training session for the subjects, it was not possible to reduce the illusory correlation. Under either the 100% or the 50% presentation conditions, training was no more effective than nontraining conditions in reducing the effect of this phenomenon. This finding is consistent with that of Chapman and Chapman (1969) and Golding and Rorer (1972). It must be recognized, however, that the training conditions in this study and in the other two just mentioned represent a limited attempt to modify a phenomenon that appears to be basic in the way people conceptualize diagnostic problems. Whether more intensive training with constant feedback and with numerous examples of faulty associational thinking would reduce the illusory correlation is a question for future research. This study supports the Chapman and Chapman (1969) position that the illusory correlation is a robust phenomenon.

Although the training conditions were not effective in reducing the illusory correlation, we replicated part of the Chapman and Chapman (1967) findings that the concept of "anality" was predominantly associated with preconceived problems of homosexuality regardless of training conditions and frequency of presentation of valid signs. A serendipitous finding was also noted in which the subjects appeared to create their own illusory correlate. That is, they created a concept of seeing "small things" and associated it significantly with problems of inferiority. Since there was no linguistic content in the stimulus material per se, it can be hypothesized that this represents a structural illusory correlate, that is, small segments of the blot rather than specific content as such. In other words, illusory correlations may span more than just simple linguistic associations. This

is an area that needs to be explored in further research.

At the end of the experiment, all of the subjects were asked for their spontaneous comments, ideas, and expectations as to what was being tested. These were recorded, and, although they do not allow any systematic quantitative analysis, they reveal that the majority of subjects expressed strong doubts as to whether the Rorschach had any valid meaning. In spite of this skepticism on the part of the subjects, the majority of them formed illusory correlations. The subjects also complained about the nature of this task, stating that it was excessively long and boring. For Groups 2 and 4 the creation of nonrandom contingencies for the Wheeler signs means that nonrandom contingencies were created for the other three categories. This experimental format, of course, is identical to that used by Chapman and Chapman. None of the subjects, however, acknowledged this either in their responses to the valid Wheeler signs or in spontaneous comments in the debriefing.

Another possible factor is the matter of potential response biases that may be imbedded in the form of the questionnaire used by Chapman and Chapman. For instance, Chapman and Chapman's (1969) questionnaire asked: "Did you notice any kind of general thing that was seen most often by men with this problem? If your answer is 'yes,' name that kind of thing and give *one* example of that kind of thing." Such instructions clearly establish a strong demand characteristic for subjects not only to find something but to pick the most easily remembered, or salient, feature. Percepts like "anus" clearly fall into this class. However, Golding and Rorer (1972) used a form of prediction feedback in their study that was expected to lead to a greater reduction in the amount of illusory correlation, but they found that the illusory correlation remained a robust one.

Also neglected in the research is the question of social pressures; that is, all subjects were tested in groups. Perhaps some felt that since others were writing down their comments, they should also be finding things, even though they themselves did not believe that the task was meaningful. In other words,

the questionnaire asked whether people had seen something, but the form of the questionnaire seems to have been interpreted by the subjects as a demand to find meaning in something that they felt was predominantly puzzling. Future research should investigate this by modifying the form or by leaving the task response more open-ended. Perhaps, providing the subjects with a range of behavioral statements about people with so-called problems, allowing them to use an actuarially designed cue sort, or allowing them to describe what they thought the predominant problems of these subjects were would produce a significantly different picture with regard to illusory correlates. With these modifications, subjects conceivably might rely less on associationally triggered responses that are paired with the diagnostic symptoms in a highly artificial, experimental paradigm.

Finally, it can be noted that the experimental arrangement developed by Chapman and Chapman (1969) does not closely approximate the traditional diagnostic process of trained clinicians and may limit the generalizability of these studies to clinical situations. Additional research might focus on attempts to do more in vivo studies of clinicians' actual conceptualizations and investigate whether the justification for the clinical

inferences can be reduced primarily to associational variables or whether in fact they represent rather illogical or irrational learning or teaching that clinicians have incorporated during their graduate education.

Avoidance-Approach: The Fifth Basic Conflict

Seymour Epstein

University of Massachusetts at Amherst

The basic conflicts are almost always listed as approach-approach, approach-avoidance, avoidance-avoidance, and double approach-avoidance conflict. The possibility of avoidance-approach conflict, in which a steeper gradient of approach intersects a gradient of avoidance, is ignored because it is assumed that approach gradients cannot be steeper than avoidance gradients, and that even if avoidance-approach conflict could exist, it would be of no interest, as the individual would simply stay away from the conflicting goal. It is demonstrated that there is no good reason for assuming that approach gradients cannot be steeper than avoidance gradients, and there is considerable evidence that they often are. It is further noted that individuals can be placed in situations not of their choosing. If an individual with an avoidance-approach conflict were placed on the goal side of the intersection of the gradients, the person would enthusiastically approach a goal that had previously been avoided. Thus, avoidance-approach conflict can account for ego-alien behavior, such as when a shy, sex-avoidant "model" boy commits a violent crime of passion. The implications and causes of avoidance-approach conflict in everyday life are discussed.

In almost all textbooks of introductory and abnormal psychology, four basic conflicts are listed with accompanying diagrams. These are approach-approach, avoidance-avoidance, approach-avoidance, and double approach-avoidance conflict. Particular attention is then given to approach-avoidance conflict, because it can account for a variety of clinical phenomena, such as that an individual in such a conflict tends to become entrapped at a midpoint from a goal and to suffer, as a consequence, from a state of heightened drive. The entrapment is explained by the assumption that the gradient of avoidance is steeper than the gradient of approach. No consideration is given to the possibility of a conflict, which I shall refer to as "avoidance-approach" conflict, in which a steeper gradient of approach intersects a gradient of avoid-

ance. There are probably two reasons why avoidance-approach conflict has been ignored. One is that it is assumed that the gradient of avoidance is necessarily steeper than the gradient of approach. The other is that it is assumed that even if a case could be made for such conflict on theoretical grounds, it would be of no practical interest, as an individual with a flatter gradient of avoidance than of approach would simply stay away from the conflicted goal. It will be demonstrated in this article that approach gradients can be steeper than avoidance gradients, and that there are important clinical phenomena, such as ego-alien behavior, that can be accounted for once this is recognized.

Lewin (1935), who originally formulated the concept of approach-avoidance conflict, simply stated without evidence that "the negative vector usually increases gradually in strength and finally becomes stronger than the positive" (p. 90). It is not clear whether he meant the word *usually* to indicate that given a negative incentive, there is usually a goal gradient, which would appear to be self-evident, or whether it was to indicate that the negative vector usually overtakes the posi-

tive. In the latter case, it would indicate that Lewin did not believe that the positive vector is always steeper than the negative one, but when it is, some interesting consequences follow.

Miller (1944) also initially assumed without explanation that avoidance gradients are steeper than approach gradients. More recently, Miller (1959) revised his position and noted that there is no intrinsic reason for avoidance gradients to be steeper than approach gradients, and that whether they are steeper or less steep depends on the extent to which the gradients are based on inner relative to outer cues. He observed that in many of the studies in which steeper gradients of avoidance were found, the avoidance gradients were based on the delivery of punishment, an external source of stimulation, whereas the approach gradients were based on hunger, an internal source of stimulation. It appears that there is no logical basis for assuming that approach gradients cannot be steeper than avoidance gradients.

As for empirical evidence on steepness of approach and avoidance gradients, it has been demonstrated that a number of factors (cf. review in Heilizer, 1977), such as stimulus differentiation (e.g., Bugelski & Woodward, 1951; Hearst, 1962; Saltz, Whitman, & Paul, 1963), number of trials (e.g., Elder, Kuehne, Clarke, & Larre, 1970; Elder, Kuehne, & Moriarty, 1970; Schroeder & Gerjuoy, 1965; Weiss, 1960), runway length (e.g., Clifford, 1973), and mental age (Tempone, 1965), are directly related to steepness of gradients. Among these, stimulus differentiation appears to be the most important factor, as it can account for the others. Thus, the finding that runway length is an important factor can be accounted for by the consideration that the greater the runway length, the more easily the end and the beginning of the runway can be differentiated (Saltz et al., 1963). The influence of number of reinforced trials can be attributed to an increase in stimulus discrimination that occurs over trials, and the influence of mental age can be attributed to the more accurate discrimination of children with higher mental age. Stimulus differentiation can also account for Miller's observation that avoidance gradients have

been found to be steeper than approach gradients when avoidance is contingent on external cues and approach on internal cues, as internal cues may not be as easily discriminated as external cues.

It follows from the above that depending on such factors as training in stimulus discrimination, number of reinforced trials, and degree to which motives are based on external relative to internal stimuli, approach gradients can be less steep, more steep, or no different in steepness from avoidance gradients. This conclusion is supported by a number of studies that have directly compared the steepness of approach and avoidance gradients. Some have reported avoidance gradients to be steeper than approach gradients (e.g., Brown, 1948; Miller & Kraeling, 1952; Miller & Murray, 1952; Murray & Berkun, 1955), some have reported approach gradients to be steeper than avoidance gradients (e.g., Hearst, 1960, 1962; Smith, 1965, 1969), and some have reported no difference in steepness of approach and avoidance gradients (e.g., Desiderato, Foldes, & Gockley, 1966; Gjesme, 1974; Hearst, 1960; Rigby, 1954).

Following an analysis of the relative steepness of approach and avoidance gradients, Maher (1966) noted that there is no firm support for the assumption that avoidance gradients tend to be steeper than approach gradients. He observed that the classic studies of Brown (1948), widely cited as evidence for the assumption, have serious methodological flaws. In a study by Maher and Nuttall (in Maher, 1966), order of testing was found to influence the relative steepness of gradients, and Maher concluded that Brown's finding of a steeper gradient of avoidance than of approach could be attributed to fatigue effects associated with order of testing. Even in studies that report no significant difference in steepness of avoidance and approach gradients, it should be considered that some subjects produced steeper gradients of approach and others of avoidance. That is, there are individual differences with respect to relative steepness of approach and avoidance gradients. In a study by Gewirtz (1959) that directly dealt with this issue, reliable individual differences were found in the relative steepness of approach and avoidance gradients. In a

Figure 1. Approach-avoidance conflict. (The individual approaches the goal when at a distance, vacillates at the intersection of the gradients, and avoids the goal when closer to it. The result is that the individual becomes trapped by his or her own motives, neither being able to fulfill nor abandon the approach motive.)

recent study in our own laboratory (Losco & Epstein, 1977), relative steepness of avoidance and approach gradients was investigated while holding magnitude and quality of incentive constant. Although a weak, significant tendency was found for the avoidance gradient to be steeper than the approach gradient, inspection of the results for individuals revealed that the phenomenon was far from uniform among subjects, with some producing much steeper approach than avoidance gradients. It was further noted that the mean tendency was not very robust and was readily canceled out by incidental factors, such as motor exertion.

Considering all the evidence together, it can safely be concluded that it is possible for approach gradients to be steeper than avoidance gradients. As already noted, Miller has come to the same conclusion. He has indicated that the only reason that he did not pursue its implications is that he found a steeper gradient of approach than of avoidance to be "less perspicuous than the other pattern" (Miller, 1959, p. 222).

A pattern in which a steeper gradient of approach intersects a gradient of avoidance not only has significant implications in its own

right, but it is important to recognize it in order to avoid confusion between approach-avoidance and avoidance-approach conflict. It is instructive, in this respect, to contrast the major features of the two types of conflict. There are three major behavioral consequences for an individual with an approach-avoidance conflict. A person with such a conflict approaches the conflicted goal at a distance, is blocked and vacillates at an intermediate point at which the gradients intersect, and retreats when closer to the goal (see Figure 1). According to Miller, the most efficacious treatment for approach-avoidance conflict is to reduce the avoidance drive, as attempting to force the individual to reach the goal can induce unmanageable levels of anxiety, and would very likely fail, since avoidance tendencies might well mount more rapidly than the combined approach tendencies. Avoidance-approach conflict also has three behavioral consequences. The individual in an avoidance-approach conflict avoids the goal when on the far side of the intersection of the gradients, is hesitant and blocked, at least momentarily, when at the point of intersection of the gradients, and exhibits an accelerated approach response if placed on the goal side of the intersection point (see Figure 2). Thus, in both approach-avoidance and avoidance-approach conflict, there are manifestations of strong avoidance reactions and of blocking and hesitation, although in the case of avoidance-approach conflict the blocking is of short duration, as movement in either direction breaks the deadlock. Considering that what is near and far from a goal and what is brief and enduring blocking are matters of judgment, it is quite possible to confuse approach-avoidance conflict with avoidance-approach conflict, unless sufficient information is obtained by observing behavior at different points along time, distance, or cue dimensions.

Perhaps the most interesting difference between approach-avoidance and avoidance-approach conflict is that only in the former case is the individual propelled into the conflict area by his or her own volition and remains trapped there. As a result, in the absence of outside pressure, the person experiences continuous tension. No such stable

equilibrium exists in avoidance-approach conflict.¹ If left to his or her own volition, the individual with an avoidance-approach conflict would simply remain out of the realm of influence of the conflict and would therefore not experience enduring stress. As already noted, this is probably one of the reasons why avoidance-approach conflict has not attracted any attention. Further consideration, however, reveals that avoidance-approach conflict is not as benign as the above analysis suggests. First, consider that the area of conflict to be avoided could be a highly significant one, such as the experience of close relationships with others. The individual with such a conflict could avoid tension only by imposing severe restrictions on his or her realm of experience. It might be argued that the limitations are imposed only by the avoidance gradient, and nothing is added by postulating an avoidance-approach conflict. After all, what function can the approach gradient play if an individual will not voluntarily expose himself or herself to its influence? The answer is that any extrinsic motive or circumstance beyond the individual's control could propel the individual to a point beyond the intersection of the two gradients. In such a circumstance, the person would exhibit behavior that is radically out of character with his or her normal behavior. The person would show an accelerating approach reaction to a goal that had been assiduously avoided up to then.

If the approach motivation involved anti-social behavior, the behavior would appear as an ego-alien breakthrough of a destructive impulse. An example of such a case is the shy, inhibited "model" boy who, suddenly faced with a temptation that he had previously succeeded in avoiding, commits a bizarre crime of passion. On the other hand, if the approach motive were a constructive one, such as the expression of socially acceptable heterosexual feelings and had been avoided because of an excessively broad fear gradient, then an accidental encounter from which withdrawal was difficult could be therapeutic. Once the individual was on the near side of the goal, there would be no further conflict, and the individual would eagerly approach a goal that had previously been avoided. With

Figure 2. Avoidance-approach conflict. (The individual avoids the goal when at a distance, is momentarily blocked at the point of intersection of the gradients, but, if placed by circumstances beyond his or her control at a closer point will rapidly and intensely approach the goal and exhibit ego-alien behavior.)

repetitive exposure to the same situation, and consequent goal attainment, the conflict would gradually be extinguished.

Given the significant consequences of pathological levels of avoidance-approach conflict, it is important to consider the conditions in real life that could give rise to it. As noted earlier, according to Miller, a critical condition for determining the relative steepness of approach and avoidance gradients is the degree to which response tendencies are influenced by inner relative to external cues. When a high proportion of inner cues is involved in an avoidance gradient, the gradient will be relatively flat and conducive to the development of avoidance-approach conflict. In humans, inner cues frequently consist of thoughts and images. To the extent that an individual is trained to believe that the expression of an impulse in any form is bad, the individual will have a broad avoidance gradient. Now consider that the same individual's approach tendencies are minimally mediated by inner responses, so that if impulses to

¹ This, of course, is also true of approach-approach conflict and of avoidance-avoidance conflict when there are no restraints against leaving the field.

approach are aroused, it is apt to be because of the presence of external cues. Such an individual would have a steeper approach than avoidance gradient, because the avoidance tendencies are internalized to a greater extent than the approach tendencies, and this could even be the case if the approach tendencies were activated by a combination of physiological and external cues, as in the sex drive.

Given sufficiently broad injunctions against the expression of an impulse in any circumstances, there is obviously no need to discriminate between the conditions in which the impulse should or should not be expressed. It will be recalled that poor stimulus discrimination is a major factor in producing broad generalization gradients. Thus, whether one wishes to analyze the comparative steepness of gradients by considering the relative contribution of inner to outer cues, or by considering the role of stimulus discrimination, one arrives at the same conclusion, namely, that strong categorical prohibitions against the expression of an impulse foster broad avoidance gradients and are conducive to the development of an avoidance-approach conflict.

The relative strengths, or heights, of approach and avoidance gradients are obviously critical factors in determining whether an avoidance-approach conflict will occur. If the approach motive is weak enough compared to the avoidance motive, the avoidance motive will, of course, dominate it at all levels, and the individual will simply exhibit a generalized avoidance tendency to all motive-relevant stimuli. The opposite will be the case if the approach motive is sufficiently strong compared to the avoidance motive. Conflict can only exist within a restricted range of relative strengths of the gradients that allows them to intersect. Given such conditions, the stronger the approach and avoidance drives, the more extreme the conflict-related phenomena that will be exhibited, and thus the greater the potential for extreme ego-alien behavior. It follows that the conditions for producing pathological levels of avoidance-approach conflict are those that foster the internalization of intense and broad prohibitions against inherently strong approach motives.

Given the above analysis of avoidance-approach conflict, it follows that overcontrolled persons are more apt to exhibit bizarre ego-alien behavior than undercontrolled persons. This conclusion is supported by studies of criminal violence, which show that the most extreme crimes are committed by individuals whose hostility is characteristically overcontrolled (cf. Blackburn, 1968; Haven, 1973; Megargee, 1966, 1971; White, McAdoo, & Megargee, 1971).

There are some interesting implications for psychotherapy that follow from an analysis of avoidance-approach conflict. For one, if the approach impulses are nondestructive, as in the case of certain sexual feelings, then persuasion, coercion, and confrontation should serve a useful role, as once the individual is brought to the goal side of the point of intersection of the gradients, the conflict will be resolved. This can be contrasted with approach-avoidance conflict, in which the same techniques are contraindicated, as pressure to approach what is feared is apt to induce unmanageable levels of anxiety and therefore cause the patient to withdraw from therapy (cf. Dollard & Miller, 1950). Thus, it is important for the therapist to discriminate between avoidance-approach and approach-avoidance conflict.

It also follows that the therapist must distinguish an avoidance-approach conflict in which the approach motive is socially acceptable from one in which it is destructive. It is obviously unwise to encourage an individual with the latter type of conflict to proceed to the goal side of the intersection point of the gradients or to lower the fear gradient, as either would result in the expression of destructive behavior. It is noteworthy, in this respect, that lowering the fear gradient is the procedure recommended by Dollard and Miller (1950) for treating approach-avoidance conflict.

The method of choice for treating an avoidance-approach conflict when the approach motive is potentially destructive is to increase discrimination of the avoidance dimension so that selective avoidance reactions against extreme and inappropriate expression of the approach motive can be substituted for

a blanket prohibition against its expression in any form.

It is interesting to consider that the differences in therapeutic approaches recommended for approach-avoidance and avoidance-approach conflicts with socially acceptable and unacceptable motives correspond to major emphases in different schools of psychotherapy. For approach-avoidance conflict, the method of choice recommended by Dollard and Miller (1950) is reduction of fear, or lowering of the avoidance motive. This appears to be appropriate when the approach motive involves socially acceptable tendencies. For avoidance-approach conflict, when the approach motive is socially acceptable, the method of choice is to induce the individual to arrive at the goal side of the intersection of the gradients. Although reduction of fear might ultimately work, other procedures, such as encouragement, coercion, and environmental manipulation provide a simpler and more efficient form of treatment. It is noteworthy that such procedures are frowned on by adherents of depth psychology, such as psychoanalysts, and by adherents of accepting forms of treatment, such as client-centered therapists, but are routinely practiced by counseling psychologists, rational-emotive psychologists, and psychodramatists. For both approach-avoidance and avoidance-approach conflicts in which the inhibited drive is destructive, the method of choice is to teach discrimination, both with respect to the stimulus dimension and the response dimension, with the aim of ultimately replacing an all-or-none system of total avoidance or total impulse expression with a system that facilitates modulated control. Schools of therapy that emphasize such an approach among other techniques include psychoanalysis, rational-emotive therapy, and, in some cases, behavior therapy.

Effective Ingredients in Psychotherapy: Prediction of Outcome From Process Variables

Beverly Gomes-Schwartz
McLean Hospital

This study was designed to examine the impact of (a) exploration of the psychodynamic roots of patients' conflicts, (b) warmth and friendliness of the therapist-offered relationship, and (c) positiveness of patients' attitudes toward working in therapy on the outcome of brief therapy with 35 college males exhibiting symptoms of depression, anxiety, and social introversion. Analyses of process ratings for audiotaped segments from four sessions throughout the course of therapy revealed that the activities of therapists of differing theoretical orientations and of professional versus untrained, "inherently helpful" therapists could be distinguished. Although patients' attitudes toward the therapist and patient involvement in the therapy process did not differ as a function of the type of therapist, the process dimension that most consistently predicted therapy outcome was patient involvement. Exploratory processes and therapist-offered relationship had a lesser influence on outcome.

Questions about how psychotherapy works—what qualities in the patient, the therapist, and the process of their interaction contribute to the amelioration of the patient's psychic distress—have generated considerable debate among proponents of varying systems of psychotherapy. Some of the issues that have prompted the widest discussion include (a) the relative importance of the patient-therapist relationship, as opposed to specialized techniques of intervention, and (b) the relevance of patients' attitudes toward the therapist and the therapy process.

Relationship Versus Technique

Rogers (1957) asserted that the consistent communication of genuine warmth and empathic understanding by the therapist is sufficient to produce constructive personality change. As long as the therapist is able to offer the patient a warm human relationship, even the most recalcitrant psychotic patients can eventually be reached (Rogers, Gendlin, Kiesler, & Truax, 1967).

In contrast, psychodynamic therapists have emphasized the importance of exploratory techniques—clarification, interpretation, confrontation—for producing the cognitive and emotional insight considered instrumental for change (Bibring, 1954; Glover, 1955; Langs, 1973). Even though a number of analytically oriented therapists have noted the significance of the patient-therapist relationship or therapeutic alliance (Greenson, 1967; Zetzel, 1956), there are fundamental differences between most dynamic therapists and the Rogerians. The analytic therapist is cautioned to maintain the role of an expert healer rather than try to be a friendly or equal partner in an interpersonal relationship. Although the trust and rapport engendered by a good therapeutic relationship may be necessary to facilitate

This article is based on a doctoral dissertation submitted to Vanderbilt University. The research was supported by National Institute of Mental Health Grant 20369 awarded to Hans H. Strupp. The contributions of members of the Vanderbilt Psychotherapy Research Team—Hans H. Strupp, Suzanne W. Hadley, Dianna Hartley, Grady Blackwood, and John Baker—are gratefully acknowledged. engagement in an exploratory process, the relationship itself traditionally has not been considered the primary force for change by analytic therapists. (For a divergent view from within the analytic mainstream on the importance of the therapeutic relationship, see Kohut, 1971.)

Empirical analyses of the relative importance of the therapeutic relationship and exploratory techniques in promoting positive change have yielded equivocal results. Although some researchers (e.g., Truax, 1963; Truax & Mitchell, 1971) were initially able to demonstrate that high levels of the relationship variables proposed as necessary and sufficient for therapeutic change by client-centered theorists (i.e., accurate empathy, unconditional positive regard, and congruence) were correlated with therapy outcome, their results have not been replicated in more recent studies (cf. Beutler, Johnson, Neville, & Workman, 1972; Garfield & Bergin, 1971; Mullen & Abeles, 1971; Sloane, Staples, Cristol, Yorkston, & Whipple, 1975). More significantly, serious criticisms of the conceptualization of the scales for measuring "therapist-offered conditions" and the methodology of much of the research have been raised (Chinsky & Rappaport, 1970; Gomes-Schwartz, Hadley, & Strupp, 1978; Gormally & Hill, 1974; Blackwood, Note 1).

Research studying other measures of the therapeutic relationship has also yielded inconsistent results. Adult outpatients in analytically oriented therapy (Feifel & Eells, 1963; Strupp, Fox, & Lessler, 1969) and clients at a college counseling center (Saltzman, Luetgert, Roth, Creaser, & Howard, 1976) who felt that their therapists were warm, understanding, and respectful of them were more likely to be satisfied with their therapy experience and to manifest improvement than were patients who saw their therapists as indifferent, bored, or irritated. In contrast, ratings based on Fiedler's (1950) measure of the "ideal therapeutic relationship" bore a minimal relationship to outcome of analytically oriented group therapy (Parloff, 1961) and no relationship to outcome of individual counseling (Gonyea, 1963; Lesser, 1961).

There has been very little sound research in which either patient or therapist participation in an exploratory, uncovering process was

related to therapy outcome. The value of Malan's (1976) finding that the frequency of interpretations linking early family experiences with the patient-therapist relationship (i.e., transference/parent links) was related to the outcome of brief psychoanalytic therapy is limited by serious methodological deficits, including the use of session notes rather than recordings or transcripts of the interviews and ratings contaminated by raters' knowledge of treatment outcomes. In contrast to Malan's results, among a sample of similar adult outpatients in dynamic therapy, Sloane et al. (1975) found that the frequency of interpretive statements was negatively correlated with improvement on target symptoms. These conflicting results suggest that the value of interpretive techniques may be largely determined by the patient's response to the interpretation. If a patient is generally resistant to self-exploration, even the most perceptive interpretations may be useless.

Unfortunately, the few studies of the relationship between therapy outcome and the patient's engagement in self-exploration (as measured from a client-centered perspective) have yielded equivocal results. Even though Truax and Carkhuff (1967) reported data from several unpublished studies substantiating their hypothesis that greater self-exploration was related to positive outcome, others (Kurtz & Grummon, 1972; Sloane et al., 1975) have found no relationship between self-exploration and outcome.

Patients' Attitudes and Behavior in Therapy

Unlike Rogers (1957), who asserted that virtually any patient could be successfully treated provided the therapist offered sufficient warmth, empathy, and genuineness, many others have suggested that the ways in which patients view their problems and the therapeutic enterprise can influence patients' responses to therapy and, consequently, the benefits that they derive from treatment. Dynamic therapists (Castelnuovo-Tedesco, 1975; Malan, 1976; Sifneos, 1972; Strupp, 1973) have asserted that appropriate therapy candidates must have both the capacity and the motivation to form an intense interpersonal relationship with the therapist and to withstand the stresses of in-

sight-oriented therapy. Although there is some empirical evidence that variables such as ego strength and motivation are related to outcome (see reviews by Gomes-Schwartz et al., 1978; Luborsky, Chandler, Auerbach, Cohen, & Bachrach, 1971; Strupp & Bergin, 1969), the amount of outcome variance that can be predicted from such pretherapy measures has generally been quite small (Auerbach, Luborsky, & Johnson, 1972; Fiske, Cartwright, & Kirtner, 1964).

More striking data on the importance of patient attitudes come from studies of behavior in early therapy sessions. Patients who were involved in the therapy process from the outset of treatment—acknowledging their own responsibility for changing their behavior and actively examining their feelings and experiences—were most likely to improve (Kirtner & Cartwright, 1958; Rice & Wagstaff, 1967; Saltzman et al., 1976). In contrast, patients who viewed their problems as externally imposed or who distanced themselves from the therapy interaction through defensive maneuvers such as intellectualization were unlikely to benefit from therapy (Kirtner & Cartwright, 1958; Rice & Wagstaff, 1967).

Frank (1973) carried the argument for the salience of patient attitudes even farther by suggesting that patients' commitment to change and expectations that therapy can help effect the changes they desire are even more important determinants of therapy outcome than the techniques that a therapist uses. Studies tapping such factors in therapy have yielded some support for Frank's position. Although there is inconsistency in the literature (Wilkins, 1973), a number of investigators have found a significant relationship between patients' expectations that they will benefit from therapy and treatment outcome (e.g., Friedman, 1963; Goldstein & Shipman, 1961; Lipkin, 1954; Martin, Sterne, Moore, & Friedmeyer, 1976). Furthermore, results from several outcome studies suggest that patients (or subjects) who believe that the "placebo" treatments they are receiving are potent therapeutic interventions may experience symptom relief comparable to that of treated patients (Frank, Gliedman, Imber, Stone, & Nash, 1959; Paul, 1966; Smith, 1976).

These results suggest that the content of the

therapist's communications (i.e., interpretation, reflection of feelings) may be less important than the patients' perceptions that they are receiving help. A logical corollary of this idea is that any concerned, helpful listener, with or without professional training as a psychotherapist, can ameliorate psychic distress if he or she offers the patient a warm, supportive relationship and if the patient has confidence in the "therapist's" abilities (Torrey, 1972; Truax & Mitchell, 1971). Empirical data on the effectiveness of nonprofessionals or "inherently helpful" listeners have been conflicting, however. Findings that untrained or minimally trained nonprofessionals were potent therapeutic agents (Carkhuff & Truax, 1965a; Poser, 1966) can be contrasted with findings that interventions by some nonprofessionals actually exacerbated symptoms (Fo & O'Donnell, 1975; Sines, Silver, & Lucero, 1961).

Reflection of Theoretical Differences in the Therapy Process

Just as proponents of client-centered, psychodynamic, and "nonspecific factors" theories of the therapeutic change process differ in their conceptualization of effective therapeutic ingredients, therapists subscribing to varying theoretical systems appear to differ in their practice of psychotherapy. Results from surveys of therapists' usual practices (Rice, Gurman, & Razin, 1974; Sundland & Barker, 1962; Wallach & Strupp, 1964) and from several studies of therapists' behavior in actual or simulated interviews (Strupp, 1955, 1958, 1960) have indicated that analytic therapists emphasized exploratory responses such as questioning and interpretation, whereas client-centered therapists consistently relied on "reflection of feelings." Although data from these studies also indicated that analytic therapists advocated a more formal, professional relationship with their patients than did Rogerian therapists, other investigators found no differences between "nondirective" (or humanistic) and psychodynamic therapists on variables such as warmth, empathy, and genuineness (Fischer, Paveza, Kickert, Hubbard, & Grayston, 1975) or insensitivity,

punitiveness, understanding, and acceptance (Fiedler, 1950).

Comparisons of professional therapists with nonprofessional "helpers" have indicated that psychotherapy training has an important impact on therapeutic techniques. In an analogue of the initial therapy interview, untrained college students emphasized leading responses, particularly direct questions (D'Augelli, Danish, & Brock, 1976). Similarly, Bohn (1965) found that in responding to tape-recorded enactments of a "hostile," "dependent," or "typical" client, relatively experienced graduate student therapists most often used responses categorized as restatement of content or clarification of feelings, whereas naive undergraduate "counselors" relied most heavily on reassurance, persuasion, direct questioning, and forcing the topic. Using a similar set of recordings, Parsons and Parker (1968) found that psychiatric residents were significantly less directive than either senior medical students or college undergraduates.

In contrast to the obtained differences in style of intervention, results from two studies indicated that nonprofessional therapists could not be distinguished from professional therapists on measures of "core conditions." Carkhuff and Truax (1965b) found that with limited training, psychiatric aides were able to offer levels of warmth and empathy comparable to those offered by advanced graduate students and experienced therapists. In initial "therapeutic" interviews, untrained college student volunteers were as warm, genuine, and empathic as experienced psychiatrists and psychiatric residents (Pope, Nudler, VonKorff, & McGee, 1974).

Hypotheses

In summary, there are varying definitions of the effective ingredients in psychotherapy. Client-centered theory emphasizes the curative powers of the good human relationship, whereas psychodynamic theory indicates that a good relationship is not sufficient to induce enduring personality change. Both the psychodynamic perspective and Frank's (1973) concept of nonspecific factors take into account the role of patients' attitudes, whereas client-centered theory carries with it the assumption that all

patients are equally amenable to therapy. In his reformulation of the concepts of the therapeutic influence, Strupp (1973) has suggested that all three elements—the quality of the relationship that the therapist offers, the reconstructive learning experiences that the therapist mediates, and the patient's willingness and capacity to engage in the therapeutic interaction—are determinants of therapeutic change. Given that there have been no attempts to examine the relative contributions of all three factors in a unified research design, the present study was designed to

1. assess the influence of theoretical orientation and psychotherapy training on the therapeutic interactions of analytically oriented, experimental, and untrained, inherently helpful counselors. Experiential therapists and nonprofessional therapists chosen on the basis of their interpersonal skill (identified as alternate therapists in this study) were expected to maintain friendlier, more personal relationships with their patients than analytic therapists. Analytic therapists and their patients were expected to engage in greater exploration of underlying psychodynamics than either experiential or alternate dyads. Alternate therapists were expected to be more directive than professionals of either theoretical orientation.

2. determine the relative impact on the outcome of therapy of (a) engagement in exploratory processes, (b) quality of the therapist-offered relationship, and (c) degree of patient involvement in the therapy interaction. Expectations concerning the relative influence of each dimension may be viewed as tests of competing theories. From the psychodynamic perspective, high levels of exploration (e.g., interpretation, clarification) and high patient involvement (e.g., willingness to communicate, trust in the therapist, recognition of the patient's own responsibility for effecting change) should be the best predictors of outcome. From the Rogerian perspective, high levels of warmth and personal involvement on the part of the therapist should be the most important predictor of change. Finally, from Frank's "nonspecific factors" perspective, both the quality of the therapist-offered relationship and the patient's attitude toward therapy should be the strongest determinants of change.

If the relationship between process and outcome

come is similar across the three groups, this would lend support to the hypothesis that common ingredients account for therapeutic change regardless of the theoretical orientation of the treatment. If, however, the therapists in each treatment group do differ on the process dimensions hypothesized as effective ingredients of psychotherapy and some of these process dimensions are relatively more potent predictors of outcome, analytic, experiential, and alternate therapists should achieve different outcomes.

Method

Subjects

Patients. The patients were 35 unmarried, male college students with elevated scores ($T > 60$) on the Depression (2), Psychasthenia (7), and Social Introversion (0) scales of the Minnesota Multiphasic Personality Inventory¹ (MMPI) who had participated in a psychotherapy outcome study. Patients had been directly referred from a university counseling center or had responded to a letter announcing a special counseling program designed to deal with difficulties in interpersonal relations, anxiety, and shyness. In previous research, similar elevations on the Depression and Psychasthenia scales had proved to be valid indicators of enduring psychological difficulties (Strupp & Bloxom, 1975).

Patients were assigned on a rotational basis to either professional or a nonprofessional therapist. Ten patients were seen by analytic therapists, 10 by experiential therapists, and 15 by alternate therapists. Patients were offered up to 25 sessions of therapy on a once- or twice-a-week basis. Mean durations of therapy for cases seen by analytic, experiential, and alternate therapists were 18.9 ($SD = 6.5$), 16.3 ($SD = 6.9$), and 17.4 ($SD = 7.2$) sessions, respectively.

Therapists. The professional therapists were four male psychiatrists (M experience = 23.5 years) and four male psychologists (M experience = 15.0 years) who were respected clinicians within the Nashville community. The psychiatrists (analytic therapists) all identified psychoanalytic theoreticians as major professional influences. In contrast, the psychologists (experiential therapists) cited the writings of Carl Rogers as having a major impact on their techniques.

The alternate therapists were seven experienced M years since PhD = 17.0) male college professors who had been identified by university administrators, other faculty, and students as teachers who were frequently approached by students for personal counseling. These professors were affiliated with a variety of academic departments including mathematics, English, history, and philosophy. Alternate therapists had been enlisted to participate in a study ostensibly to determine whether inherently helpful people without formal psychotherapy training could aid college students in dealing with their problems in much the same ways that

professional therapists did. They were instructed to behave in the therapy sessions as they usually did when students consulted them for personal advice or counseling. They were specifically advised not to make a special effort to read about psychotherapy.

Instruments

Process scales. To measure the process of psychotherapy, it was necessary to use an instrument that was sufficiently sensitive to capture the quality of the interaction, yet did not require the rating of dimensions so abstract as to preclude reasonable interrater agreement. The Vanderbilt Psychotherapy Process Scale (VPPS; Strupp, Hartley, & Blackwood, Note 2), an 84-item, Likert-type scale, adapted from earlier work by Orlinsky and Howard (1967) to rate the therapy hour from the perspective of a clinical observer, seemed an appropriate instrument.

In an earlier study with a smaller sample of subjects, eight internally consistent subscales derived from the instrument by a priori content analysis successfully discriminated among the three treatment groups—analytic, experiential, and alternate (Gomes-Schwartz & Schwartz, 1978). However, these original scales did not seem to precisely tap the process dimensions that were hypothesized as predictors of therapy outcome. To obtain another perspective on how the individual items might be related, a principal components factor analysis with varimax rotation² was performed on the data from the Gomes-Schwartz and Schwartz (1978) study. Rotated factors with eigenvalues > 1 were defined by items loading $\geq .50$.

From these factors seven scales were derived that tapped dimensions hypothesized as predictors of outcome and that proved to be internally consistent and reliably rated in the present study. (a) Patient Exploration (7 items, coefficient $\alpha = .83$, interrater $r = .88$) gauged the patient's level of self-examination and exploration of feelings and experiences. (b) Therapist Exploration (7 items, $\alpha = .91$, $r = .93$) gauged the degree to which the therapist attempted to examine the psychodynamics underlying the patient's problems. (c) Patient Participation (7 items, $\alpha = .86$, $r = .76$) tapped the degree to which the patient was actively engaged in the therapy interaction (e.g., initiating discussions, not inhibited, etc.). (d) Patient Hostility (6 items, $\alpha = .84$, $r = .82$) measured the level of negativism, hostility, or distrust displayed by the patient. (e) Therapist Warmth and Friendliness (10 items, $\alpha = .83$, $r = .60$) measured the therapist's warmth, caring, and emotional involvement with the patient. (f) Negative Therapist Attitude (3 items, $\alpha = .65$,

¹ Scores on Scales 2, 7, and 0 were not necessarily the only elevations or the highest elevations on the patient's profile. Thus not all of the patients could be categorized as 2-7-0s.

² Although factor analysis is often of questionable value with small samples, it was felt that this technique might generate some meaningful combinations that had been overlooked in the a priori content analysis.

$r = .85$) gauged attitudes that might be expected to threaten or intimidate the patient. (g) Therapist Directiveness (5 items, $\alpha = .88$, $r = .83$) measured directive interventions such as offering advice and modeling behavior. Although this scale was expected to discriminate professional from nonprofessional therapists, a relationship between Therapist Directiveness and treatment outcome was not predicted.

Outcome measures. In previous psychotherapy research (cf. Cartwright, Kirtner & Fiske, 1963; Garfield, Bergin, & Prager, 1971), correlations between outcome indices have generally been low. Therefore, it seemed important to assess treatment effects from several perspectives. Three global and three individualized measures of outcome were selected.

At the conclusion of treatment, both the therapist and an experienced clinical interviewer rated change (6-point Likert-type scales) in (a) severity of the patient's problems; (b) level of the patient's distress; and (c) quality of the patient's functioning in his social, work, and academic roles. Scores on the three items were summed to yield, respectively, therapists' and clinicians' overall ratings of improvement. Global improvement from the patient's perspective was assessed through residual gain scores on an Minnesota Multiphasic Personality Inventory (MMPI) index of malad-

justment (Cooke, 1967). To obtain the MMPI maladjustment score, each of the standard MMPI scales plus Welsh A, Welsh R, and Barron Es were assigned beta weights and summed.

Patients', therapists', and clinicians' ratings of improvement on the target complaints that patients had presented at the outset of therapy were used as more individualized outcome indices. Since patients had been permitted to specify up to three problems that they wished to resolve in therapy, scores were based on the average change across all of the patient's targets.

Procedure

Two advanced clinical psychology graduate students who were not familiar with any of the therapists in the study were selected as raters to reduce the possibility of ratings being biased by knowledge that a therapist was not a professional or by raters' expectations about a therapist based on prior experiences with him.

To provide a broad representative sample of the interaction audiotaped segments from the third interview, the interviews one half and three fourths of the way through treatment and the next-to-last interview were selected for rating. Starting at a randomly deter-

mined point in each recording (e.g., 11, 19, 13 minutes from the beginning), the succeeding 10-minute segment was recorded onto a master tape such that the segments from all cases and all sessions were presented in random sequence. Independent ratings were made at the conclusion of each 10-minute segment. Since there were no systematic differences in process scores attributable to the time sequence of the segment, all $F_s(3, 96) \leq 1.44$, *ns*, or the interaction of time sequence and treatment group, all $F_s(6, 96) \leq 2.01$, *ns*, overall scores for each process scale were obtained by summing across both the two raters and the four segments.

Results

Differences Among the Treatment Groups

Process variables. To test the hypothesis that therapy interactions differed according to the theoretical orientation or professional-nonprofessional status of the therapist, differences among the three groups—analytic, experiential, and alternate—on the seven process scales were assessed through a multiple discriminant analysis. This analysis, presented in Table 1, yielded a significant overall difference among the groups (Wilks' $\lambda = .08$), $F(14, 52) = 9.22$, $p < .0001$. Examination of differences on individual variables using Dunn's multiple comparison procedure (Dunn, 1961) revealed that the hypothesized relationships among treatment groups were generally obtained.

Both alternate and experiential therapists exhibited greater Therapist Warmth and Friendliness than analytic therapists ($p < .01$). Analytic cases received higher scores than either experiential or alternate cases on Therapist Exploration ($p_s < .05$ and $.01$, respectively) and Patient Exploration ($p_s < .01$ and $.001$, respectively). In addition, the experiential group received higher ratings than the alternates on both Patient Exploration ($p < .01$) and Therapist Exploration ($p < .01$).

The hypothesis that alternate therapists would receive higher ratings than analytic and experiential therapists on Therapist Directiveness received partial support. Alternate therapists were more directive than analytic therapists ($p < .01$). However, experiential therapists did not differ from alternates and were significantly more directive than the analytic group ($p < .01$).

No differences among groups were obtained on ratings of Patient Participation, Patient Hostility, and Negative Therapist Attitude.

Clinicians			
<i>M</i>	1.73	1.69	1.97
<i>SD</i>	1.25	1.79	1.90

Note. Wilks $\lambda = .69$; $F(12, 54) = .92$, *ns*. All univariate $F_s(2, 32) < 1$.

^a For all variables except Minnesota Multiphasic Personality Inventory (MMPI) maladjustment, higher scores indicate greater change.

^b $n = 10$.

^c $n = 15$.

Outcome variables. A discriminant function analysis comparing the treatment groups on the six outcome criteria yielded neither a significant overall difference (Wilks $\lambda = .69$), $F(12, 54) = .92$, *ns*, nor differences on individual outcome criteria (see Table 2).

Prediction of Outcome from Process Dimensions

The relationship between psychotherapy process and outcome was examined in several ways to determine (a) which process dimensions (i.e., exploratory processes, patient involvement, therapist-offered relationship) were the best predictors of outcome, (b) whether the relationships between process dimensions and outcome variables were primarily due to the contribution of individual dimensions or

to the interactions among the dimensions, and (c) whether the relationship between process and outcome was consistent across treatment groups.

Since each of the process dimensions hypothesized as a predictor of outcome was tapped by two process scales (i.e., exploratory processes = Patient Exploration and Therapist Exploration; patient involvement = Patient Participation and Patient Hostility; therapist-offered relationship = Therapist Warmth and Friendliness and Negative Therapist Attitude), multiple regression analyses predicting each of the outcome variables from each pair of process scales were performed. Results from these analyses, presented in Table 3, indicated that patient involvement was consistently the best predictor of outcome. Multiple correlations of patient involvement with clinicians' and therapists' overall improvement ratings and therapists' ratings of improvement in target complaints were significant. In addition, multiple correlations of involvement with improvement in patients' and clinicians' target complaints approached significance ($p < .10$). In contrast, exploratory processes predicted only therapists' overall improvement ratings ($p < .05$), and therapist-offered relationship predicted only improvement in therapists' target complaints ($p < .01$).

Not only did patient involvement bear a significant relationship with more outcome variables than the process dimensions, in each

case in which another process dimension was significantly correlated with outcome, but patient involvement accounted for more of the variance in outcome ratings (i.e., 30% vs. 18% for exploratory processes and 38% vs. 24% for therapist-offered relationship).

Since the three process dimensions cannot be regarded as independent (e.g., the patient's attitude may be influenced by the therapist's behavior), it was necessary to determine whether the significant multiple correlations represented the interactive effects of more than one process dimension or were primarily determined by a single dimension. Thus, partial correlations between each process dimension and each outcome variable with the effects of the remaining two process dimensions partialled out were computed (see Table 4). These analyses revealed that patient involvement exclusive of the influences of both exploratory processes and therapist-offered relationship showed a consistent relationship with outcome. Four of the six partial correlations between involvement and outcome variables were significant. In contrast, none of the partial correlations between exploratory processes or therapist-offered relationship and outcome approached significance.

To determine whether the observed relationships between process and outcome were similar for the three treatment groups (analytic, experiential, and alternate), it was necessary to test whether the multiple regression slopes

Table 4
Partial Correlations Between Process Dimensions and Outcome Variables

Outcome variable	Exploratory processes	Patient involvement	Therapist-offered relationship
Overall ratings			
Clinicians	.08	.49**	-.05

** $p < .01$.

depicting the relation of the three process dimensions to each outcome variable differed across treatment groups. F tests for homogeneity of regression yielded no significant effects, all F s(6, 23) \leq 1.59, ns , indicating that the relationship between process and outcome was consistent regardless of the theoretical orientation or professional status of the therapist.

Discussion

The primary findings in this study were as follows: (a) Theoretical orientation and professional-nonprofessional status of the therapist had an impact on the process but not the outcome of psychotherapy; and (b) therapy outcome was most consistently predicted by the patient's willingness and ability to become actively involved in the therapy interaction—a dimension of therapy process that did *not* distinguish among the three treatment groups.

As predicted, professionally trained therapists, particularly those with an analytic orientation, and their patients invested more effort in uncovering the psychodynamic roots of the patient's problems than did the dyads led by nonprofessional therapists. Therapists with experiential training and the untrained counselors offered warmer, more personal relationships with their patients than did therapists who assumed an analytic stance. These findings are largely consistent with the psy-

chotherapeutic theories to which the therapists subscribed. The analyst has traditionally been taught to remain aloof—an expert healer rather than a warm friend (Langs, 1973). In contrast, warmth, empathy, and genuineness are considered to be the fundamental tools of the client-centered therapist (Rogers, 1957). Perhaps the emergence of "self" theory in psychoanalysis with its increased focus on the importance of the therapist's capacity to respond empathically (see, for example, Kohut, 1971) may eventually challenge traditional notions concerning the appropriate analytic posture and blur some of the distinctions between client-centered and dynamic therapists' self-presentations in therapy. However, as the behavior of the analytic therapists in this study may illustrate, the therapist who has assumed the traditional passive, non-demonstrative role for many years may find it difficult to relinquish.

Even though the therapists for each of the three treatment groups behaved quite differently, these differences did not seem to influence patients' attitudes toward therapy or the therapist. Patients were as likely to become involved in the therapy process regardless of whether they saw analytic, experiential, or alternate therapists. The fact that the patient's willingness to ally himself with the therapist and work at changing was not influenced by the theoretical orientation and professional status of his therapist may be of particular importance for understanding why there were

no differences among the groups on treatment outcome. These patient characteristics that did *not* distinguish the three treatment groups consistently emerged as the best predictors of therapy outcome. Patients who were not hostile or mistrustful and who actively contributed to the therapy interaction achieved greater changes than those who were withdrawn, defensive, or otherwise unwilling to engage in the therapy process.

How can the findings from this study best be accommodated with theories of therapeutic influence? The results are clearly congruent with Frank's (1973) theory of "nonspecific factors" as the determinants of outcome. Given mildly to moderately disturbed patients in short-term therapy (an average of 17.4 sessions), untrained professor/therapists generally affected as much improvement as experienced psychologists and psychiatrists. Further, the variables that best predicted change were not related to therapeutic techniques but to the positiveness of the patient's attitude toward his therapist and his commitment to work at changing.

The present findings are also consonant with the ideas of specialists in brief psychoanalytic therapy that those patients who have the willingness and the adaptive resources to work with the therapist to resolve their problems are most likely to profit from short-term therapy (Castelnuovo-Tedesco, 1975; Malan, 1976; Sifneos, 1972). Although there is little evidence in this study that the use of exploratory technique also strongly influenced outcome as analytic theory would suggest, it is possible that technique variables might have been more salient if treatment were of longer duration (e.g., the 40-session limit proposed by Malan, 1976, or the maximum of 1 year suggested by Sifneos, 1972) or if only patients "appropriate" for brief dynamic therapy (i.e., those with sufficient motivation and ego resources) were selected for treatment. If difficulties in maintaining self-esteem, which a considerable portion of the patients in this study exhibited, can be viewed as indicators of narcissistic pathology, Kohut's (1971) proposal that patients with severe pathology in the area of the "self" benefit less from dynamic interpretation than from the empathic attention of the therapist may also aid in explaining

why proficiency in dynamic exploration bore so little relation to outcome in this sample.

If the patient's capacity and willingness to participate in the therapy interaction are among the most important determinants of improvement in short-term therapy, one of the aims of future research should be to determine if and how positive involvement in therapy could be increased. It is essential to determine the extent to which the patient's negativism or inability to collaborate reflects (a) relatively stable personality characteristics or (b) response to psychonoxious attitudes and behaviors on the part of the therapist.

If as some therapists (Castelnuovo-Tedesco, 1975; Sifneos, 1972) and researchers (Kirtner & Cartwright, 1958; Rice & Wagstaff, 1967) have suggested, the patient's ability to actively work toward resolving problems is a reflection of an enduring character structure or life view, researchers may be able to detect evidence of a generalized sense of hostility or passive indifference in the patient's interactions with others (e.g., an intake interviewer). Finding that the degree to which patients become positively involved in the therapy process was influenced by long-standing personality characteristics would have important implications for therapy practice.

One option for maximizing the effectiveness of psychotherapy would be to select only those patients who evidence a capacity to actively participate in a therapeutic interaction. Rather than offering psychotherapy, particularly uncovering therapy, to all patients who present themselves at a clinic or community mental health center, clinicians might consider alternative interventions for applicants who did not appear to have the capacity to ally themselves with a therapist or to assume a great deal of the responsibility for changing themselves.

Another approach might be to alter some of the behaviors that prevent patients from succeeding in psychotherapy. If patients' abilities to become involved in the therapy process were as much a product of inappropriate expectations about the psychotherapy enterprise as a lack of willingness to take responsibility for their own behavior, role-induction procedures (cf. Hoehn-Saric et al., 1964; Strupp & Bloxom, 1973) might be useful to demonstrate to pro-

spective patients what types of behaviors would be expected of them in therapy.

Even if enduring attitudes were a major determinant of a patient's capacity to become involved in therapy, there are very likely some therapist behaviors that can prompt or exacerbate negativism, defensiveness, or apathy. Determining the therapist behaviors, attitudes, or character traits that interact with patient attitudes to influence involvement may have important implications for the selection and training of therapists and for the "matching" of optimal patient-therapist pairs.

In conclusion, the results of this study have illustrated that meaningful measures of psychotherapy process are possible, and that outcome can be predicted from the process of the therapy interaction. However, additional questions about the role of the patient and the therapist in determining the course of therapy have been raised. It is reasonable to hope that some of these questions can be answered through continued research efforts.

Coping and the Self-Control of Chronic Tension Headache

Kenneth A. Holroyd and Frank Andrasik
Ohio University

Thirty-nine community residents with chronic tension headache were assigned to one of two self-control treatment groups, a headache discussion group, or a symptom-monitoring control group. Participants in the two self-control treatment groups and in the headache discussion group were provided similar rationales for treatment and were taught to monitor their cognitive responses to stress-eliciting situations. Participants in the two self-control treatment groups were also taught either cognitive or both cognitive and relaxation coping skills for controlling tension headache. Participants in the headache discussion group were not provided with specific skills for controlling their headaches but were led in a discussion of the historical roots of their symptoms. Both the self-control treatments and the headache discussion procedure produced substantial reductions in headache that were maintained at a 6-week follow-up. The symptom-monitoring control group showed no change in headache symptoms. These findings provide additional evidence of the effectiveness of cognitively oriented therapeutic procedures for the treatment of tension headache but raise questions concerning the active ingredients of these treatments.

Headache may be the most commonly reported bodily complaint (Wolff, 1963). Survey data indicate that between 50% and 70% of adults experience headaches, 40% of which are tension headaches (Kashiwagi, McClure, & Wetzel, 1972). Of the 15 classes of headache identified by the Ad Hoc Committee on Classification of Headache (1962) of the American Medical Association, tension headache, also commonly termed muscle contraction, psychogenic, or nervous headache, is the most frequently occurring. Tension headache is typically characterized by persistent sensations of bandlike pain or tightness located bilaterally in the occipital and/or forehead regions. It is gradual in onset and may last for hours, weeks, or even months.

The exact etiology of tension headache

remains unclear (Bakal, 1975). However, there is a general consensus that tension headache (a) is an individual response to psychological stress (Ad Hoc Committee on the Classification of Headache, 1962; Wolff, 1963) and (b) may result from the sustained contraction of skeletal muscles about the face, scalp, neck, and shoulders (Bakal, 1975; Martin, 1972).

Behavioral approaches to the treatment of tension headache have focused on modifying the muscle contraction responses presumed to contribute to tension headache (Budzynski, Stoyva, Adler, & Mullaney, 1973; Cox, Freudlich, & Meyer, 1975; Haynes, Griffin, Mooney, & Parise, 1975; Hutchings & Reinking, 1976). However, a somewhat different approach was taken by Holroyd, Andrasik, and Westbrook (1977), who found that a self-control treatment that focused on modifying cognitive responses to stress-eliciting situations was more effective in reducing tension headaches than biofeedback-assisted relaxation training when these treatments were accompanied by counterdemand instructions. The self-control treatment used in Holroyd et al. contained cognitively oriented thera-

Appreciation is expressed to Dale Mattmiller, Henrietta Russell, and Teresa Abell who assisted with the carrying out of this experiment. This study was supported by Grant 1-R03-MH28939-1 from the National Institute of Mental Health to the first author.

peutic procedures (Beck, 1976; Goldfried, Decentecio, & Weinberg, 1974; Meichenbaum, 1977) to teach individuals to identify their reactions to stress and to use effective cognitive coping skills. Similar treatment procedures have been found effective not only for the treatment of clinical problems such as specific anxieties (Di Loreto, 1971; Goldfried, Linehan, & Smith, 1978; Holroyd, 1976; Meichenbaum, 1972; Meichenbaum, Gilmore, & Fedoravicious, 1971; Kanter & Goldfried, Note 1), depression (Rush, Beck, Kovacs, & Hollon, 1977), stuttering (Moleski & Tosi, 1976), and unassertive behavior (Thorpe, 1975; Wolfe & Fodor, 1977; Linehan & Goldfried, Note 2) but also for providing individuals with skills for coping with laboratory (Meichenbaum, Turk, & Burnstein, 1975) and real-life (Langer, Janis, & Wolfer, 1975) stressors.

In light of growing evidence of the effectiveness of such cognitive self-control treatments, it becomes important to determine to what extent the various components of these treatments contribute to the effectiveness of the treatments. Although such complex social influence procedures are difficult to dissect, recent analyses (Beck, 1976; Goldfried, 1977; Holroyd et al., 1977; Meichenbaum, 1977) suggest that these treatment procedures at least influence clients to (a) attribute the source of their symptoms to relatively specific cognitive aberrations rather than to external stimuli or complex inner dispositions; (b) identify or self-monitor a cognitive component of their distress; and (c) engage in specific cognitive coping strategies (e.g. reappraisal, self-instruction, imagery, etc.). The present study attempted to determine to what extent the specific coping strategies that are taught during treatment contribute to treatment outcome.

Chronic headache sufferers were assigned to one of two self-control treatment groups, a headache discussion group, or a symptom-monitoring control group. Participants in the two self-control treatment groups and in the headache discussion group were provided similar rationales for treatment designed to influence them to adopt similar cognitively oriented explanations for their symptoms, and were taught to monitor their cognitive

responses to stress-eliciting situations in a similar manner. Participants in the two self-control treatment groups were also taught either cognitive coping skills or both cognitive and relaxation skills for managing stress and controlling tension headache. Participants in the headache discussion group were provided no specific skills for managing stress or controlling headaches. However, since previous work has indicated that a treatment procedure consisting solely of the treatment rationale and instruction in the monitoring of cognitive responses to stress lacks credibility, an alternate therapeutic task involving a discussion of the historical sources of headache symptoms was provided for this group. Symptom-monitoring control group members recorded their headaches but did not receive treatment until the study had been completed.

Method

Subjects

Articles in local newspapers, appearances on radio "talk shows," and wall posters were used in addition to newspaper, radio, and television advertisements to circulate announcements of a program teaching methods for the self-control of tension headache to communities within a 50-mile radius of Athens, Ohio. Telephone and small group screening procedures, as well as evaluations by participants' physicians, were used to identify those individuals exhibiting clear-cut symptoms of tension headache occurring consistently at least three times per week from 123 initial respondents. Participants included 35 females and 4 males with a mean age of 35.2 years and a mean duration of headache symptoms of 10.1 years.

Procedure

Following initial telephone screening, potential participants were seen in small groups by one of the authors, who obtained informed consent and a required \$5 deposit, administered pretreatment measures, and arranged to obtain diagnostic medical information. A list of 19 characteristics of tension headache was also used to eliminate volunteers suffering from other types of headache or reporting mixed headache symptoms (Wolff, 1963). Tension headache sufferers who reported consistently experiencing a minimum of three tension headaches per week were assigned by a within-sample matching technique (Goldstein, Heller, & Sechrest, 1966) to one of the two self-control treatments, the headache discussion group, or to the symptom-monitoring control group.

Measures

Symptoms. For at least 2 weeks prior to receiving treatment, continuing through a 2-week post-treatment assessment, and for 2 weeks at a 6-week follow-up evaluation, participants maintained a headache data card on which they rated the occurrence and intensity of headaches on an 11-point scale (0 = no headache, 10 = incapacitating headache) every hour from 10:00 a.m. through 10:00 p.m. (Haynes et al., 1975). An index of overall headache activity was calculated by summing headache ratings each day with weekly averages.¹ In addition, participants' ratings of the frequency of occurrence of 18 common psychosomatic complaints were obtained on the psychosomatic checklist (Cox et al., 1975) at pretreatment, posttreatment, and follow-up evaluations.

Frontalis electromyographic (EMG) activity. Frontalis EMG was assessed during resting periods at pretreatment evaluation and, for participants receiving treatment, following each treatment session. While participants rested in a heavily padded chair, in a different location from where they received treatment, frontalis muscle activity was monitored from forehead disk electrode placements (Budzynski et al., 1973) directed to a Cyborg BL933 electromyograph. Three 1-minute integrated EMG measurements were sampled and averaged to provide an index of frontalis muscle activity.

Additional measures. To assess their perceptions of the credibility of the treatment that they received, the participants evaluated the probability of their recommending the treatment to a friend suffering from tension headache and how important they felt it was that their treatment be made available to other headache sufferers (on 5-point scales) following the first treatment session, at posttreatment, and at follow-up evaluations. Participants also rated the warmth, empathy, and skill of their therapist at the posttreatment and follow-up evaluations. Since it was suspected that the headache discussion procedure might increase participants' levels of self-esteem without necessarily reducing specific symptoms, self-esteem was assessed by the Miskimins Self-Goal Other Discrepancy Scale (Ryan, Krall, & Hodges, 1976) at all three assessments. No attempts were made to influence participants' medication intake. However, medication intake was recorded on a daily basis on the headache data cards.

Treatment

Treatment procedures were administered during five weekly 1½-hour group meetings. We each conducted one group of each type so that therapists and groups were completely crossed. Although we both have had previous experience in treating chronic tension headaches with self-control procedures in an individual format (e.g., Holroyd et al., 1977), the first author had somewhat more group therapy experience (5 years) than the second author, who had conducted one group previous to this study. Counter-demand instructions emphasizing that no improve-

ment could be expected until the completion of treatment (Steinmark & Borkovec, 1974) were administered at the end of the first treatment session.

Cognitive self-control ($n=10$). This treatment focused on altering maladaptive cognitive responses that were assumed to mediate the occurrence of tension headache. The treatment format closely followed that used by Holroyd et al. (1977), with appropriate modifications for the group setting. Specific procedures were adapted from cognitively oriented therapy procedures (Beck, 1976; Goldfried et al., 1974; Meichenbaum, 1977) and were designed to maximize the occurrence of causal reattribution and the development of self-monitoring and cognitive coping skills described below.

The rationale for treatment emphasized that disturbing emotional and behavioral responses are a direct function of specifiable maladaptive cognitions. It was emphasized that tension headache results from psychological stress and that stress responses are determined by cognitions about an event or situation. Several concrete examples were provided to illustrate the variety of events that can be perceived as stressful by different individuals and the way in which cognitions can induce psychological stress and headache. In addition, unreasonable expectations (that one should be perfect or liked by everyone) were discussed, and the manner in which these expectations predispose individuals to experience stress was illustrated.

Following presentation of the treatment rationale each group member constructed a list of stressful situations. The therapist, working in turn with each group member, focused on identifying (a) the cues that trigger tension and anxiety, (b) how the client responded when anxious (withdrawal, passivity, etc.), (c) the clients' thoughts prior to becoming aware of tension while tense and subsequently, and (d) the way in which these cognitions appeared to contribute to the clients' tension and headache. Clients were encouraged to learn from group members who proved most adept at this cognitive analysis and to assist other group members in identifying cognitive components of their distress.

As soon as clients became fluent at verbalizing cognitions associated with feelings of distress, they were instructed to deliberately interrupt the sequence of covert events preceding their emotional response at the earliest possible moment. To do this clients were instructed to use signs of impending distress as a signal to engage in cognitive strategies incompatible with the further occurrence of cognitive stress responses. The therapist verbally modeled (Kazdin, 1973) strategies that were designed

¹ Average weekly headache activity scores (HA) were computed by the following formula: $HA = (I \times D)$, where I is intensity of headache and D is the hours of duration of headache. This index of headache is considered to be the most useful measure of headache activity, as it incorporates two separate dimensions of each reported headache.

to enable clients to use each of the three main types of intrapsychic coping responses that have been identified by Lazarus and his co-workers (Lazarus, Averill, & Opton, 1974): cognitive reappraisal, attention deployment, and fantasy. Clients were encouraged to practice these coping skills on a daily basis and to implement these cognitive coping skills at the first sign of headache following the third treatment session.

Combined cognitive and relaxation self-control ($n=10$). This treatment focused on altering both cognitive and muscle contraction responses to stressful situations. The treatment format was similar to that used in the cognitive self-control groups except that muscle relaxation was also taught as a self-control skill (Goldfried & Trier, 1974) for coping with psychological stress and tension headache.

The rationale for this treatment emphasized that tension headache resulted from both psychological stress and sustained muscle contraction responses. Clients were encouraged to monitor both their cognitive responses to stress and their perceived level of muscle tension in stressful situations. In addition to the cognitive coping strategies provided to clients in the cognitive self-control group, clients were taught to use muscle relaxation as a coping skill. Relaxation training followed procedures outlined by Bernstein and Borkovec (1973), with particular attention to facial, neck, and forehead muscles, which are thought to be associated with tension headaches. Approximately equal portions of each session were spent on teaching cognitive and relaxation coping skills. Clients were encouraged to practice muscle relaxation at home on a daily basis and to implement these coping skills at the first sign of headache following the third treatment session.

Headache discussion. This treatment focused on a discussion of the historical roots of symptoms rather than on the development of specific coping skills. Although clients were taught to monitor their cognitive responses to stress in the same manner as they were in the other two treatment groups, no strategies for coping with stress were provided.

The rationale presented for this treatment also described headaches as resulting from psychological stress but emphasized that feelings of distress would improve if clients understood the underlying source of their problems. Group members were encouraged to examine the thoughts and feelings that accompanied their headaches for clues that might be provided to the underlying source of their symptoms. The basic procedures followed by the therapist were designed to increase the clients' self-confidence and self-esteem and to provide a reasonable explanation for the clients' distress in terms of historical events in their lives. The therapist encouraged clients to openly discuss and explore their emotional responses to stressful life events, emphasized similarities among the problems and reactions of group members, and, where possible, offered plausible interpretations designed to link previous life events with current emotional reactions and problems. ("Your anxiety appears to be a natural reaction to the way you

were treated as a child.") The therapists deliberately avoided suggesting specific methods for coping with stress and attempted to prevent other group members from offering this type of advice.

Symptom-monitoring control ($n=10$). Participants assigned to this group recorded their headaches in the same manner as other participants in the study but were informed that due to the large number of applicants, treatment would not be available until a later date. Participants assigned to this group returned their headache data cards by mail on a weekly basis. To maximize compliance with this procedure, they were paid \$10 for accurately recording their headaches.

Six of the initial 39 participants were eliminated prior to data analysis. Two participants withdrew from treatment: 1 participant in the combined group reported that she was uncomfortable participating with another member of her group whose child she taught at school; another participant in the headache discussion group reported that the self-monitoring was exacerbating his headaches. In addition, schedule conflicts prevented 2 participants in the combined group and 1 participant in the headache discussion group from attending a minimum of three sessions. One participant in the symptom-monitoring control group also reported that she lost her headache data cards. Follow-up data were unavailable for 1 participant in the headache discussion group who moved out of state.

Results

Examination of pretreatment scores, presented in Table 1, reveals occasional differences among groups. Although separate analyses of variance revealed that none of these differences were significant, analysis of covariance (with pretreatment scores as the covariate) was used to provide the most accurate assessment of treatment effects.

Headache Recording

Average weekly headache activity scores are presented in Figure 1. Although both self-control groups and the headache discussion group showed substantial reductions in headache activity that were maintained at follow-up, the symptom-monitoring control group showed essentially no change in headache activity.

Analysis of covariance revealed highly significant treatment effects at both posttreatment and follow-up assessments, $F(3, 28) = 7.1$, and $F(3, 27) = 11.8$, respectively, both $ps < .001$. t tests for correlated means re-

vealed that both self-control groups and the headache discussion group showed significant improvements at posttreatment and follow-up assessments (at least $p < .05$), whereas the symptom-monitoring control group showed no change in headache activity. Duncan's new multiple-range test conducted on adjusted posttest and follow-up means further revealed that the two self-control groups and the headache discussion group differed significantly from the symptom-monitoring control group ($p < .05$) but not from one another.

Pretreatment and adjusted posttreatment and follow-up means for additional component measures of headache (frequency, duration, and intensity) are presented in Table 1. Results from separate analyses of covariance conducted on these measures revealed significant

treatment effects on all three of these measures (at least $p < .05$ at follow-up), with the pattern of results very similar to that reported for the composite headache activity score discussed above.

To examine possible therapist differences in outcome, headache activity scores for participants in the three treatment conditions were subjected to Treatment \times Therapist analyses of covariance. Significant therapist effects were obtained at both posttreatment and follow-up assessments, $F(1, 17) = 6.0$, and $F(1, 16) = 6.1$, both $ps < .025$. At both assessments participants treated by the first author obtained somewhat lower adjusted headache activity scores (posttest $M = 26.9$, follow-up $M = 25.9$) than participants treated by the second author (posttest $M =$

Figure 1. Mean weekly headache activity scores in 2-week blocks. (Foll = follow-up.)

79.9, follow-up $M = 58.9$). However, t tests for correlated means revealed that participants treated by each of the therapists showed significant improvements in headache activity at both assessments (at least $p < .01$). Thus, even though both therapists produced significant reductions in headache activity, reductions by the first author were of a somewhat larger magnitude. Similar analyses conducted on the additional component headache activity scores revealed significant therapist effects on headache duration ($p < .05$) but not on headache frequency or intensity.

Additional Measures

Analysis of covariance conducted on posttest and follow-up psychosomatic checklist frequency scores revealed significant treatment effects at both assessments, $F(3, 28) = 4.2$, $p < .02$, and $F(3, 27) = 4.7$, $ps < .01$, respectively. Although t tests for correlated means revealed that only the cognitive self-control group and the headache discussion group reported fewer psychosomatic symptoms following treatment ($p < .01$), Duncan's test indicated that only the headache discussion and combined cognitive and relaxation

self-control groups differed significantly at posttest ($p < .01$). No therapist differences were observed on this measure. Differences among the four groups in self-esteem approached but did not reach significance, $F(3, 28) = 2.7$, $p < .07$. No differences were observed among the four groups in the number of participants taking medication for their tension headaches, $\chi^2(3) = .28$. However, of the 28 participants taking medication, 17 of 20 participants receiving treatment recorded reductions in the frequency of their medication intake at follow-up, whereas only 1 of 8 participants not receiving treatment recorded reductions (Fisher's exact probability test, $p = .0007$). Correlational analyses revealed no significant relationships between demographic variables, headache history, or self-esteem scores and headache improvement.

Electromyographic Activity

Examination of pretreatment means presented in Table 1 reveals that the severe headache symptoms exhibited by participants in this study were not accompanied by similarly elevated levels of resting frontalis muscle tension. Thus, to the extent that increased mus-

cle tension is associated with headache symptoms exhibited by these individuals, this muscle tension must be elicited by a limited range of, probably, stressful situations. Analyses of covariance revealed that differences in EMG activity among the two self-control groups and the headache discussion group only approached significance at posttest, $F(2, 20) = 2.1, p < .10$. Also, EMG reductions were not significantly correlated with improvements in headache symptoms.

Therapist and Treatment Ratings

It can be seen in Table 1 that both self-control treatments and the headache discussion procedure were rated as highly credible treatments at all three evaluations. However, analyses of variance revealed significant differences in the ratings of these procedures following the first treatment session, $F(2, 29) = 4.9, p < .05$, but not at posttreatment and follow-up assessments. Duncan's test revealed that the headache discussion procedure was rated as slightly less credible than the combined cognitive and relaxation treatment ($p < .05$), whereas the cognitive treatment did not differ from either of the other procedures. The two therapists were rated as equally warm, empathetic, and skillful by participants in their respective groups. However, neither therapist ratings nor treatment ratings were significantly correlated with headache improvement.

Discussion

Results from the present study complement those obtained by Holroyd et al. (1977) in showing that cognitive self-control procedures can provide an effective treatment for chronic tension headache whether they are administered individually or in a group. The group administration used in the present study resulted in reductions in headache activity that were comparable to those obtained when the treatment was individually administered in Holroyd et al. This suggests that therapist time might be effectively conserved by the group administration of these procedures. In addition, these results add to a growing body of evidence (Beck, 1976; Goldfried, 1977;

Mahoney & Arnkoff, in press; Meichenbaum, 1977) supporting the effectiveness of therapeutic procedures designed to alter clients' cognitions in the treatment of anxiety and stress-related disorders.

However, additional findings from the present study raise questions about the effective procedural ingredients of such cognitive therapeutic procedures. Neither the elimination of cognitive coping strategies from the cognitive treatment used in the present study nor the addition of self-control relaxation to this treatment altered its effectiveness. Thus, the positive outcomes that were obtained with this treatment do not appear to have resulted from the specific cognitive coping strategies that were provided. Somewhat similar results have been obtained by Thorpe, Amatu, Blakey, and Burns (1976) who found that not only was the effectiveness of rational emotive therapy not enhanced by the addition of specific self-instructional coping strategies, but the combined procedure was less effective than rational emotive therapy alone on some measures.

Participants in the two self-control treatment groups and in the headache discussion group were interviewed following treatment to obtain additional information concerning the methods that they used to control their headaches. Although all participants in the two self-control groups reported using the self-control procedures that they were taught during treatment, it is of note that all but one of the participants in the headache discussion group also reported devising cognitive self-control procedures for coping with their tension headaches. These strategies appeared to distract the users from worrisome thoughts and/or to enable them to reevaluate the stressor situation. Although the reported methods for controlling headaches were often strikingly similar to those used by participants in the two self-control groups, several individuals developed somewhat unusual methods for managing their headaches. For example, one woman began praying when she noted cognitive symptoms of distress, and she indicated that a brief period of prayer enabled her to approach previously stressful situations with some detachment. A man imaginably engaged in karate exercises. He

reported that these imaginary exercises distracted him from his worries and allowed him to "get a handle" on himself. The only participant who did not report engaging in specific cognitive strategies for coping with headache also showed only minimal improvement in headache activity. These results suggest that the improvements shown by participants in the headache discussion group may have resulted from their use of cognitive coping strategies of their own devising.

Results from other studies that have compared the combination of cognitive therapy and relaxation training procedures with cognitive procedures alone have obtained results consistent with the present findings, indicating that the addition of relaxation training to cognitive interventions does not enhance their effectiveness. Thus, even though combined treatments have been found to be less effective than cognitive interventions (Holroyd, 1976; Meichenbaum et al., 1971; Kanter & Goldfried, Note 1) and equally effective as cognitive interventions (Novaco, 1975; Osarchuk, 1977), they have not been shown to be more effective than cognitive interventions alone. A number of investigators have explained these findings by assuming that clients are unable to master both of these techniques in the brief treatment time typically allowed in these studies (Goldfried, 1977; Meichenbaum et al., 1971). Although frontalis EMG activity was not assessed during relaxation training, the fact that participants in the combined treatment group did not show significant reductions in EMG level following treatment suggests that these individuals may not have adequately mastered the relaxation training procedure. On the other hand, the posttreatment EMG levels of participants in this group were comparable to the post-treatment EMG levels achieved by participants in other studies using relaxation training procedures (Budzynski et al., 1973; Haynes et al., 1975; Hutchings & Reinking, 1976). Thus, the failure to obtain reductions in frontalis muscle activity may have resulted from the initially low resting EMG levels exhibited by participants in this study.

Frontalis muscle activity was not significantly associated with headache symptoms prior to treatment, and reductions in EMG

activity were not correlated with headache improvement following treatment. This weak association between resting levels of frontalis EMG activity and tension headache has been found in a number of recent studies (Cox et al., 1975; Epstein & Abel, 1977; Haynes et al., 1975; Holroyd et al., 1977). It seems likely that muscle contraction responses to specific stressful situations might contribute to tension headaches even though these responses might not be elicited in the relaxed laboratory assessment situation. Therefore, research on tension headache would probably benefit from the development of methods for assessing such responses to laboratory or real-life stressors.

The fact that both the self-control and headache discussion treatments yielded similar outcomes suggests that elements common to these interventions may have accounted for their results. For example, the provision of a causal explanation for distressing symptoms may have served to increase clients' belief in their ability to cope with their symptoms (Frank, 1974; Murray & Jacobson, *in press*). Although somewhat different explanations of the therapeutic process were provided in each of the groups, they all emphasized that clients could master their symptoms. Thus, specific cognitive distortions or muscle contraction responses eliciting tension headache could be combated by engaging in specific coping responses or by understanding their historical antecedents, which were no longer present and therefore need not influence current responses. Such explanations, which increase an individual's belief in their ability to cope with previously debilitating symptoms, might be expected to lead to a greater initiation and persistence of coping behavior (Bandura, 1977). Similarly, training in identifying a cognitive component of distress may have facilitated control of tension headaches by sensitizing clients to early signs of psychological stress, thus providing cues for appropriately engaging in coping responses (Meichenbaum, 1975). It may be less crucial to provide clients with specific coping responses than to insure that they monitor the insidious onset of symptoms and are capable of engaging in some sort of cognitive or behavioral response incompatible

with the further exacerbation of symptoms. Clearly, further research will be required to determine the way that these factors contribute to therapeutic change.

Although clients seen by each of the therapists showed substantial reductions in headache activity, somewhat larger reductions in headache activity were obtained by one of the therapists. Since no differences in outcome were observed when similar treatments were ministered individually in a previous study (Holroyd et al., 1977), the differences obtained in the present study may have resulted from therapist differences in experience with group therapy procedures.

Comparison of Linear and Configural MMPI Diagnostic Methods With an Uncontaminated Criterion

Ronald A. Giannetti, James H. Johnson, Daniel E. Klingler,
and Thomas A. Williams

Department of Psychiatry, University of Utah

Previous studies of linear and configural Minnesota Multiphasic Personality Inventory (MMPI) diagnostic predictors have suffered from varying degrees of criterion contamination. We replicated and extended previous findings with 572 subjects who had been diagnostically classified without MMPI contamination. The Goldberg linear equations derived from MMPI group profiles achieved 84% accuracy in classifying group profiles and a 14% increment over base-rate accuracy in classifying individual profiles. The Goldberg linear equation and several configural methods for discriminating psychotics from neurotics were compared. The linear equation was found to be most accurate. Conflicting results in previous articles suggest that criterion contamination must be avoided in prediction studies. A possible use for the group profile classification equations in evaluating experimental studies is suggested.

Several configural rules and linear indices have been developed to diagnostically classify Minnesota Multiphasic Personality Inventory (MMPI) profiles. Peterson (1954) specified a number of signs that discriminated patients who later become schizophrenic. These signs are (a) *T* scores on four or more clinical scales greater than 70; (b) *F* greater than 65; (c) *Sc* greater than *Pt*; (d) *Pa* or *Ma* greater than 70; (e) *Pa*, *Sc*, or *Ma* greater than *Hs*, *D*, and *Hy*; and (f) *D* greater than both *Hs* and *Hy*. Taulbee and Sisson (1957) developed rules to discriminate the profiles of schizophrenics from those of neurotics. Their method compares 16 scale pairs for elevation and tallies the number of pairs that differ in the scored direction. Experimental results have shown this method to be more accurate than the judgment of clinicians. Meehl and Dahlstrom (1960) constructed and cross-validated a highly complex, multistep, configural algorithm for discriminating the profiles of psychotics from neurotics. They elucidated the central assumption of the configural approach, namely, that the infor-

mation required to make discriminations resides primarily in nonlinear relationships among MMPI scales.

Goldberg (1965, 1969) challenged this assumption in two comprehensive studies that compared numerous techniques for discriminating psychotic from neurotic MMPI profiles. His results indicated that a five-variable linear composite of MMPI scales ($L + Pa + Sc - Hy - Pt$) was superior to previously developed configural rules, profile typologies, actuarial tables, several nonlinear (e.g., Bayesian) actuarial techniques, and clinicians' judgments in making the psychotic/neurotic discrimination.

Goldberg (1972) also applied the linear model to group profiles. He hypothesized that his procedure results in indicators of underlying processes that are more useful than results derived from individual profiles. His rationale was that the process of averaging individual profiles reduces the error, or "noise," inherent in individual profiles and results in a clearer "signal" of underlying processes. Goldberg classified Lanyon's (1968) compilation of MMPI group profiles into the molar diagnostic categories of psychotic, neurotic, sociopathic, and normal. He then

Requests for reprints should be sent to Ronald A. Giannetti, Department of Psychiatry and Behavioral Science, Box 1980, Norfolk, Virginia 23501.

developed a set of three linear equations, which are applied sequentially to group profiles for diagnostic sorting. The first equation separates normals from psychiatric groups. The second separates sociopathic from psychiatric groups. The final equation separates the remaining groups into psychotic and neurotic. This procedure classified profiles with remarkable accuracy (93%-99%). In addition, the linear equation, earlier derived from individual profiles to discriminate psychotics from neurotics, was replicated for group profiles. These results provide support for the use of linear rather than configural systems for MMPI profile classification.

However, the issue of configural rules versus linear combinations has not been conclusively resolved. In each of the studies cited above, there was some criterion contamination; the MMPI results were used in varying degrees to determine the criterion diagnoses that were being predicted. Goldberg (1965) was aware of this difficulty and reanalyzed his individual profile data after dividing his sample into groups considered to be "least contaminated" and "most contaminated." The results of these analyses suggested that criterion contamination may have had significant effects on the predictive validities. In the least contaminated sample, there was no difference between the predictive validities of the Goldberg equation and the Meehl-Dahlstrom rules. He also found that if one assigns a rank order to scores by elevation to the eight psychopathology scales, the sum of the ranks of *D*, *Hy*, and *Pt* (the most elevated scale receives a rank score of 1; low scores are considered neurotic) has the highest validity coefficient in the least contaminated sample. Thus, although the preponderance of his results favored the linear equation, one configural method equaled and another outperformed it.

In a replication study, Goodson and King (1976) compared the predictive accuracy of the Peterson signs and the Goldberg equation. In contradiction to Goldberg's results, they found the Peterson signs to be superior in two samples. However, the criterion diagnoses in one sample were based entirely on the MMPI and, hence, were contaminated. Their findings were unclear as to whether the MMPI contributed to the diagnoses in the second sample.

The present study was undertaken to replicate and extend certain of the results of the above studies using an uncontaminated criterion. The purposes of this study were to (a) attempt to replicate Goldberg's (1972) results with group profiles; (b) estimate the diagnostic classificatory accuracy of the equations derived from group profiles when applied to individual profiles; and (c) compare the relative classificatory accuracy of the various "cookbook" methods for discriminating psychotic from neurotic profiles (specifically, the Goldberg equation, the Meehl-Dahlstrom rules, the sum-of-ranks rule, the Taulbee-Sission signs, and the Peterson signs).

Method

Subjects

The sample was composed of male veterans who were evaluated at the time of application for treatment at the Psychiatric Assessment Unit of the Salt Lake City Veterans Administration Hospital. Subject selection was limited to those veterans who completed the experimental evaluation and testing within 48 hours of referral. In addition, all subjects whose MMPI had more than 30 missing items or had an *F-K* dissimulation index (Gough, 1950) greater than 14 were eliminated. This resulted in a sample of 572 subjects classified into seven psychotic groups ($n = 218$), three sociopathic groups ($n = 208$), three neurotic groups ($n = 88$), and one "no mental illness" group ($n = 58$). The mean age for the sample was 37.7 years ($SD = 12.4$). The mean IQ estimated from the Shipley-Hartford (Paulson & Lin, 1970) was 103.4 ($SD = 12.7$).

Instrumentation

The Current and Past Psychopathology Scales (CAPPS) structured recording form for evaluating current and past psychopathology and social functioning (Endicott & Spitzer, 1972) was used as the diagnostic data base form. The CAPPS consists of 41 items about current psychopathology and 130 items about past psychopathology, personality characteristics, and academic, occupational, and interpersonal adjustment. It is a rationally constructed instrument that was developed to provide coverage of symptoms generally considered to be important in the evaluation of diagnosis, severity of illness, and prognosis. Endicott and Spitzer have shown that interjudge reliabilities for individual items are very high (range = .68-1.00). For purposes of this experiment, the CAPPS was used as data input to the DIAGNO II diagnostic program (Spitzer & Endicott, 1969). The DIAGNO II program was rationally constructed to mimic the clinician's diagnostic reasoning, given ratings on the CAPPS items as the source of input information. This program has

been shown to produce diagnoses that agree with standard clinical diagnoses as well as experienced clinicians agree with each other and at the same time to reduce situational diagnostic bias (Spitzer & Endicott, 1969).

Subjects were also administered the booklet form of the MMPI and the Shipley-Hartford.

Procedure

CAPPS interviews were administered by three staff members (a clinical psychologist, a social worker, and a nurse) who had been trained using materials provided by Jean Endicott. The order of administration of the CAPPS and MMPI was dependent on the availability of an interviewer. In those instances in which the MMPI was administered prior to the CAPPS, the interviewer had no knowledge of the MMPI results.

Although previous research with the CAPPS has shown that well-trained interviewers produce highly reliable item ratings, the interjudge diagnostic reliability of the staff members was studied. An additional sample of 30 male applicants for psychiatric care served as subjects for this study. Three interviewers recorded CAPPS ratings for each of the subjects. These ratings were input to DIAGNO II. Output consisted of 30 sets of three diagnoses made using the *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association, 1968). The kappa technique, developed by Fleiss (1971) for measuring nominal agreement among raters, was used to compute interjudge diagnostic reliability. The value of kappa was .45 for all diagnoses for the 30 subjects. This value was significantly greater than zero ($p < .001$) and somewhat greater than the mean of the mean of kappas ($\kappa = .40$) reported by Spitzer and Fleiss (1974) for 12 specific diagnoses in their review of seven diagnostic reliability studies.

A previous study on our patient population showed that experienced senior clinicians agree with DIAGNO-II diagnoses no better than with the treatment clinicians' diagnoses (Klingler, Miller, Johnson, & Williams, 1977).

To cross-validate the predictors of group profiles, a mean profile was calculated for each of the diagnostic groups. Group profiles were then scored on the relevant predictors derived in Goldberg's (1972) study (normal vs. psychiatric, $Hs + 2Pd - Ma$; psychiatric vs. sociopathic, $2Pd - Hy - Sc$; and psychotic vs. neurotic, $L + Pa + Sc - Hy - Pt$). The means and standard deviations of these scores were calculated over the number of mean profiles in the psychotic, sociopathic, and neurotic categories. Only the mean could be calculated for the no mental illness group.

The diagnostic accuracy of the equations derived for the group profiles was then tested on individual profiles. Since these equations are applied sequentially, and since we lacked information about the expected distribution of group differences to set cutting scores, the following steps were taken: First, the mean and standard deviation for each equation were calculated for the portion of the sample to which they would be

applied. Thus, for the "normal versus psychiatric" equation, these statistics were calculated over the entire sample. For the "psychiatric versus sociopathic" equation, these calculations were made with the no mental illness group removed, and so forth. Second, assuming a normal distribution of scores on the predictors, the cutting scores for classification were set such that the selection ratio would equal the diagnostic base rates when each equation was applied.

The psychotic versus neurotic predictors were subjected to two analyses for comparability with Goldberg's (1965) results. Because the Meehl-Dahlstrom rules and Taulbee-Sisson signs permit an indeterminate classification, the Goldberg equation and the sum-of-ranks rule were also permitted an indeterminate classification. Using Goldberg's cutting scores, the indeterminate ranges were designated as scores between 40 and 49 on the Goldberg equation and scores of 11 or 12 on the sum-of-ranks rule.

A second analysis was performed to force a prediction for each case, because an indeterminate range has not been designated for the Peterson signs. In this analysis only the Goldberg equation, the sum-of-ranks rule, and the Peterson signs could be compared. The cutting points for predicting psychosis were scores greater than 45 for the Goldberg equation, greater than 11 for the sum-of-ranks rule, and more than 2 signs present for the Peterson signs.

One further procedure was necessary to insure comparability to Goldberg's results. His analyses were based on a sample that approached a 50% split between the criterion diagnoses. The present sample contained far more psychotics than neurotics. Thus, all 88 individuals with neurotic diagnoses were included in the analysis. An equal number of psychotics was selected by randomly sampling from each of the seven psychotic diagnoses in proportion to the number of individuals receiving each diagnosis.

Results

Analysis of the group profiles confirms Goldberg's results. Table 1 displays the means and standard deviations obtained on the group profile predictors and those obtained in Goldberg's (1972) derivation sample. Despite the small sample of groups in this study, the separations among the groups were very large and in the expected directions. The poorest separation was between psychotics and neurotics; yet, the means were more than two standard deviations apart, one-tailed $t(8) = 2.95$, $p < .01$. Since a test of significance does not necessarily imply a strong degree of statistical association (Hays, 1963), it was decided to calculate the omega-square for this contrast. The value of ω^2 was .44, suggesting a strong degree of discrimination between groups. Further evidence for the strength of

Table 2

Valid Positive Predictions for Individual Profiles Using Group-Profile-Derived Predictors

Category	Valid positives (%)	n
Schizophrenia, paranoid type	59	22
Other major affective disorder	58	19
Psychotic depressive reaction	50	36
Schizophrenia, catatonic type	50	16
Schizophrenia, chronic undifferentiated type	44	84
Acute schizophrenic episode	39	23
Schizophrenia, schizoaffective type	28	18
Total psychotic	46	218
Drug dependence	66	44
Unspecified alcoholism	52	130
Antisocial personality	50	34
Total sociopathic	54	208
Hysterical neurosis	50	22
Depressive neurosis	25	32
Anxiety neurosis	19	34
Total neurotic	36	88
No mental illness	19	58
Total sample	45	572

these results was obtained by applying the cutting scores for the classification equations suggested in the derivation study to this sample. Only 2 of the 14 group profiles were misclassified: "depressive neurosis" and "no mental disorder." This represents 86% accuracy of classification in a small replication sample.

These equations were then used to sequentially classify the 572 individual profiles. After each equation was applied, the fourfold hit-miss table was analyzed using McNemar's test for correlated proportions (Siegel, 1956). This was done to test the hypothesis that the distribution of predictions was not significantly different from the distribution of diagnoses. Since a hypothesis of no difference was being tested, the significance level was set at .10 to avoid a Type I error. The one-tailed chi-square values ($df = 1$) for the three prediction stages were .01, 1.6, and 2.2, respectively ($p > .10$).

Table 3

Comparison of Four Methods for Discriminating Psychotics From Neurotics Permitting an Indeterminate Classification

Method	Hits		Misses		Indeterminate	
	<i>n</i>	%	<i>n</i>	%	<i>n</i>	%
Goldberg equation	95	65.5	50	34.5	31	17.6
Sum of ranks (<i>Hy</i> , <i>D</i> , & <i>Pt</i>)	77	55.8	61	44.2	38	21.6
Meehl-Dahlstrom rules	63	46.7	72	53.3	41	23.3
Taulbee-Sisson signs	45	45.9	53	54.1	78	44.3

Note. Hit-miss percentages are based on the number of profiles classified.

The distributions of predicted and criterion diagnoses were not significantly different.

Table 2 displays the hit rates for each specific diagnosis, each molar diagnostic category, and the total sample. The sequential approach was most accurate in identifying characterological and psychotic syndromes (with the exception of schizoaffective schizophrenia) and least accurate in identifying the no mental illness profiles. Random assignment of profiles to the molar diagnostic categories, given base rates, should produce an expected hit rate of 31%. For all subjects the hit rate was 45%, a 14% improvement over chance accuracy.

Results of the comparison of the various methods for discriminating psychotics from neurotics, with an indeterminate category permitted, are shown in Table 3. These results confirm Goldberg's findings. The Goldberg equation resulted in the most hits, the fewest misses, and left the fewest individuals unclassified. Calculating a phi coefficient on the fourfold hit-miss contingency table on individuals for whom a prediction was made yielded a $\phi = .320$, $\chi^2(1) = 14.85$, $p < .0005$. The sum-of-ranks rule yielded a $\phi = .121$, which did not achieve significance, $\chi^2(1) = 2.01$, $p > .10$. Surprisingly, the Meehl-Dahlstrom rules and the Taulbee-Sisson signs achieved less than chance accuracy, and the latter left nearly 45% of the sample unclassified.

Results with the indeterminate category excluded are shown in Table 4. In this analysis the Goldberg equation again was the most accurate, followed closely by the Peterson signs. The sum-of-ranks rule did not produce a significant result.

Discussion

The results obtained in discriminating psychotics from neurotics support Goldberg's previous results, which suggest the superiority of the linear model over configural methods. However, it is noted that none of the presently available linear, sequential-linear, or configural methods works very well in predicting diagnostic categories from individual profiles. In each case the incremental accuracies obtained above the base rates were quite modest. Even though actuarial methods are accurate in classifying groups, they appear to have little validity for the practical clinical problem of classifying individuals.

The present findings also serve to highlight the potent effects of criterion contamination. In Goldberg's (1965) most contaminated sample, the Meehl-Dahlstrom rules and the Taulbee-Sisson signs achieved the creditable validity coefficients of .42 and .40, respectively. These coefficients fell to .29 and .27 in the least contaminated sample. In the present study both methods resulted in accuracy below chance. In addition, a number of other pre-

Table 4
Comparison of Three Methods for Distinguishing Psychotics From Neurotics, Excluding an Indeterminate Classification

Method	% hits	ϕ	χ^2
Goldberg equation	61.9	.239	10.09*
Peterson signs	60.8	.216	8.23*
Sum of ranks	55.7	.114	2.28

Note. $df = 1$ for chi-squares.

* $p < .005$ ($n = 176$).

dictors in the 1965 study showed the opposite effect on their coefficients; they had lower validities in the more contaminated sample. This suggests that criterion contamination must be scrupulously avoided. If it occurs, even to a slight degree, results obtained from such data can be misleading.

Despite possible difficulties with Goldberg's (1972) group profile derivation sample, this technique appears quite robust on cross-validation. This replication lends greater credence to the argument that group averaging serves to filter out much of the measurement error inherent in individual profiles, revealing a composite variable closely related to the criterion. Unfortunately, the high degree of accuracy in classifying groups does not generalize to classifying individuals.

The accuracy of group classification procedures may be used to advantage in evaluating research about psychopathology. Many studies of pathological groups report MMPI mean scores. Two procedures are commonly used to relate the findings of these studies to the MMPI. The mean profile of a group is interpreted as if it were an individual profile, and the percentage of the most frequently appearing two-point codes in the group are reported. Although these procedures are useful for descriptive purposes, application of the sequential formulae to the group mean profile would provide strong evidence as to which population the group under study was drawn from: normal, sociopathic, neurotic, or psychotic.

This may be illustrated by two examples from the recent literature. Rader (1977) compared the MMPIs of three groups of men arrested for either indecent exposure, assault, or rape. The mean profile of the exposure group was within normal limits, with *Pd* being the most elevated. Rader concluded that the exposure group was comprised primarily of mild nonconformists who occasionally test societal limits. The sequential formulae result in a sociopathic classification for this mean profile. This indicates that the exposure group is more deviant than visual inspection of the mean profile would suggest. In another study, Widom (1977) tested the efficacy of an advertisement for recruiting noninstitutionalized psychopaths for experimental study.

Applying the Goldberg rules to the mean profile of 23 men recruited by this procedure results in a sociopathic classification.¹ This corroborates Widom's findings that a sample of psychopaths had been recruited by this method. Thus, Goldberg's linear combinations are a valuable adjunct for interpreting group results.

¹ MMPI scale scores were estimated visually from a figure in the study.

Longitudinal Study of Marital Success and Failure

P. M. Bentler and Michael D. Newcomb
University of California, Los Angeles

Personality and background questionnaires were administered to newly married couples. Four years later these couples were followed up to determine their marital status and satisfaction. Our findings indicate that (a) correlational similarity as well as mean differentiation between partners was higher in the still-married group than the divorced group; (b) accuracy of self-perception was marginally reflective of marital success; (c) living together before marriage had no apparent effect on the outcome of marriage; (d) divorced couples appeared to face qualitatively different problems than married couples; and (e) longitudinal prediction of marital adjustment was possible, with prediction based on signed, equal weights yielding $R \cong .70$. It appears that variation in marital outcome is most accurately predicted from personality and not demographic variables, based largely on data from women.

This study attempts to clarify the role of marital partners' personality traits on the success or failure of their marriage. We gathered information on background, personality, and peer assessment of personality variables at the beginning of the marriages in our sample. Four years later we determined the outcome of these marriages in terms of staying together or divorcing and the quality of these marriages using a marital adjustment scale. We then compared the separated or divorced with the still-married couples in terms of the variables that we had assessed at the earlier period. Since our independent variables—personality and background data—were assessed at the beginning of the marriages, we were able to construct several useful regression equations to predict marital adjustment.

There have been only a few longitudinal

studies addressed to the question of what draws people together as couples and what keeps them there once joined. Several of these studies focus on factors that contribute most toward a couple deciding to marry or to separate before marriage (Burgess & Wallin, 1953; Hill, Rubin, & Peplau, 1976; Udry, 1967). This study addresses a different segment in the marriage process, beginning with the marriage itself. We wanted to know how and which personality traits, brought to the marriage by each partner, affected the subsequent outcome and quality of that marriage 4 years later. This is an old problem; Kelly (1939) and Terman and Oden (1947), both using longitudinal designs, addressed a similar question. Their assessment of personality was in the form of a general personality factor that could not be broken down into identifiable or logical components. They were looking for the overall contribution of "personality," as a global concept, to the outcome of marriage. The present study has assessed a wide variety of heterogeneous personality traits in order to specify personality to a much greater extent. Burgess and Wallin (1953) have also studied engagement and marital adjustment longitudinally. They eliminated divorced or separated couples from their sample, looked only at intact marriages, and used the Thurstone Personality Inventory, designed to as-

This report was prepared for the International Conference on Love and Attraction, University College of Swansea, Wales, September 1977. The investigation was supported in part by a Research Scientist Development Award (K02-DA00017) and Research Grant DA01070 from the U.S. Public Health Service. The assistance of Bonnie Barron, Leslie Hutcherson, Marion Hee, and George Speckart is gratefully acknowledged.

sess primarily neurotic problems, which, as Tharp (1963) pointed out, makes the results less applicable to a nonpathological population.

Trait research has also generated many cross-sectional studies of married and divorced groups. Even though personality traits included in recent research have focused more on those that are specifiable and nonneurotic, the question of causation or prediction has remained clouded and unanswered in cross-sectional designs (DeYoung & Fleischer, 1976; Locke, 1951; Murstein & Glaudin, 1966; Pickford, Signori, & Rempel, 1966a, 1966b; Singh, Nigam, & Saxena, 1976). Whereas the causative effects of background characteristics can reasonably be studied cross-sectionally in that they are not subject to change by the passing of time or the pressures of marriage, this cannot necessarily be said for personality traits. If one studies a marriage failure cross-sectionally, one does not know whether the personality pattern was the cause or consequence of marital breakup.

The current research has attempted to avoid these pitfalls by longitudinally studying a wide variety of nonpathological personality traits and the effects that they have on marital outcome. Since the nature of our study does not permit the use of initial random assignment nor the manipulation of personality variables, it represents something less than the ideal longitudinal experiment. Yet, the design would seem to be quite functional within these constraints. Our general hypotheses were that (a) those marriages that are still intact will have shown, at the beginning of their marriage, more similarity (homogamy) of partners on personality traits and background items than the separated or divorced couples (Barton & Cattell, 1972; Cattell & Nesselroade, 1967; DeYoung & Fleischer, 1976; Kernodle, 1969; Murstein, 1961, 1967; Singh et al., 1976; Holz, Note 1); (b) there will be a greater peer-self agreement on personality for the still-married couples than for the split marriages (Murstein & Beck, 1972; Weigel, Weigel, & Richardson, 1973); (c) living together before marriage will increase the probability of marital success; (d) problems of a married

couple will be qualitatively different than problems of a divorced couple; and (e) significant longitudinal prediction of marital success based on traits and demographics is possible.

Method

Sample

Our original sample consisted of 162 newly married couples solicited from the rolls of the local marriage license bureau. After follow-up 4 years later, our working sample consisted of 77 couples: 53 were still married, and 24 had separated or divorced. The attrition in sample size was primarily due to the inability to contact many couples, as well as death in two instances. At the time of follow-up, we received responses from 89% of the deliverable letters, which seems reasonably high. Los Angeles is a highly mobile community, which made recontacting the original sample extremely difficult. Only a very small percentage of our original couples lived at the same address 4 years after initial contact with them. Nonetheless, we do not feel that our sample reduction has been caused by any systematic bias; it represents a fair sample of couples under realistic field conditions. All studies of this type have problems with sampling bias (e.g., volunteer bias, motivation) that we feel are unavoidable. This bias should not invalidate the results, but it stresses the importance of replication.

All demographic data (e.g., age, education, occupation) were assessed at the beginning of the marriage. The mean age of the males in our working sample was 27 years old and ranged from the late teens to the 60s. They were predominantly Caucasian—only three minorities—and the majority of their religious choices were split between "none" and Protestant. Their mean educational level achieved was "some college," ranging from the eighth grade to the doctoral level. Their mean occupational level was lower-middle class and ranged from lower class to upper-middle class (seven class levels were considered: lower, working, low to upper middle, low-upper, and upper).

The mean age of the women in our final sample was 24 and ranged from the late teens to the 60s. Their race and religious affiliations were similar to the males. Their mean educational level achieved was "some college" and ranged from the eighth grade to the master's level. Their mean occupational level was middle-middle class and ranged from working class to upper-middle class.

The average length of time for knowing each other before marriage was 2 years. This ranged from a minimum of 6 months to a maximum of 8 years. Twelve percent did not get engaged. For those couples who did get engaged, the average length of engagement time before marriage was 5 months and ranged from less than 1 month to over 3 years.

Initial Data Collection

We used the Bentler Psychological Inventory (BPI), which assesses 28 personality traits (Comrey, Backer, & Glaser, 1973). The BPI consists of 680 pairs of statements, with each pair representing two poles of a single dimension. The respondent is asked to choose the one item of each pair that most closely reflects himself/herself. Although the BPI

was developed with multivariate methods, the items are fairly face valid so that the results indicate how the person views himself/herself. Table 1 provides a listing of the 28 trait-scale names. Brief descriptive examples of high and low rankings on each scale are given in columns 2 and 3. Columns 4 and 5 show the internal consistency coefficients for a standardization sample of the self- and peer-inventories, respectively (Bentler, Note 2). The last column pro-

Table 1
Personality Trait-Scale Descriptions

Scale name	Rank		Statistical characteristics ^a		
	High	Low	Self K-R 20 ^b	Peer K-R 20 ^b	Self- Peer <i>r</i>
Agility	Quick reflexes	Clumsy	.92	.93	.50
Ambition	Seek status; want to be well-known	Satisfying position is OK	.95	.95	.47
Art Interest	Like museums and the fine arts	Not concerned with art exhibits	.94	.94	.69
Attractiveness	Nice face; sexy	Homely; plain; average features	.96	.95	.39
Body weight	Thin; skinny	Husky; fat	.98	.97	.77
Cheerfulness	Playful; happy	Moody; serious	.93	.94	.54
Clothes consciousness	Fastidious dresser; neat	Sloppy; sometimes unkempt	.95	.95	.73
Congeniality	Good-natured	Impatient; stern	.88	.92	.44
Deliberateness	Premeditated; careful	Impulsive; rash; make few plans	.93	.95	.41
Diligence	Energetic	Lazy; dawdler	.94	.94	.50
Extraversion	Pushy; talker	Shy; reserved	.95	.95	.64
Flexibility	Give in; pliable	Obstinate	.87	.92	.43
Generosity	Spender; sharer	Selfish; miserly	.93	.95	.48
Intelligence	Intellectual	Mentally average	.93	.91	.52
Invulnerability	Thick-skinned; not easily hurt	Sensitive; easily hurt	.94	.95	.38
Law Abidance	Must be legal	Rules can be bent	.89	.92	.60
Leadership	Domineering	Follower	.95	.96	.60
Liberalism	Like social protest and change	Conservative	.89	.90	.65
Masculinity	Read sports page; mannish	Like to sew; read social page	.96	.96	.94
Objectivity	Scientific	Superstitious	.87	.87	.60
Orderliness	Organized; neat	Messy; careless	.96	.97	.55
Perceptiveness	Empathetic; aware	Can't tell other's feelings	.86	.93	.25
Religious commitment	Believe in God; like church	Atheist; don't go to church	.94	.94	.76
Self-acceptance	High self-esteem; happy with self	Feel worthless; bad self-image	.95	.97	.50
Stability	Relaxed; composed	Tense; nervous	.94	.95	.44
Thriftiness	Buy on sale; save coupons	Don't shop around	.92	.93	.48
Travel interest	Take trips often; traveler	Stay at home; rarely take trips	.92	.95	.44
Trustfulness	Faith in people	Often disbelieve	.93	.93	.41

^a Based on Bentler (Note 2); *n* = 216.

^b Kuder-Richardson 20 internal consistency coefficient.

vides the peer-self correlations based on the standardization data, representing the cross-correlations between BPI and the Bentler Interactive Psychological Inventory (BIPI) scales. The BIPI is identical to the BPI but is directed at the description of another person. It is generally filled out by a peer or knowledgeable observer of a subject. In the current study, the BIPI was filled out by a friend of the husband or wife in reference to the husband or wife, respectively, representing peer evaluations of personality.

The Sexual Behavior Inventory consists of a listing of 20 sexual activities, based on Bentler (1968a, 1968b). The couple was asked to answer in a yes/no manner which of these behaviors they, as a couple, have engaged in.

Background information was obtained for both individual partners, as well as on their relationship. For each individual information was collected on age, height, weight, race, religion, education, occupation, previous divorce (or death of spouse), previous children, and parental divorces. In regard to the couple, it was ascertained how long they had known each other, been engaged, and, if applicable, lived together before marriage.

Follow-Up Data Collection

Our follow-up questionnaire had two sections. The first section consisted of the Locke and Wallace (1959) Marital Adjustment Scale, which we scored by their methods. The second section consisted of 3-point ratings (no problem = 0, moderate problem = 1, extreme problem = 2) of 19 potential problem areas. This was scored by weighted summation across all problem areas. One questionnaire was completed by each still-married couple and by as many divorced people as could be located. A score was calculated for each section on which questionnaires had been completed by both partners; in a divorced marriage, we averaged the respective scores. In total, we obtained this information on 68 couples. Although it might have been preferable to have had each partner of an intact marriage complete a questionnaire separately, we felt that we would have no control over whether in fact they had been completed independently. To determine how much variation was introduced by having still-married couples complete a single questionnaire, we included an item that asked them to assess the extent of agreement or disagreement that they had experienced while completing the form. On a 6-point rating scale (from always agreed to always disagreed), 98% reported that they had always agreed or almost always agreed. The remaining 2% indicated that they had occasionally disagreed. It can be argued that having the questionnaire completed differently by the two groups may have some effect on the validity of the measure. Although this hypothesis cannot be confirmed or denied, the procedure we used seemed the most feasible.

A factor analysis of the adjustment scale revealed substantial positive loadings of all items on the first

unrotated factor, which accounted for 75% of the variance. Thus, the scale assesses a fairly unidimensional quality. Since the first and second part scores were significantly correlated, $r(66) = -.78, p < .001$, indicating that marital adjustment and lack of problems were positively related, a composite score was obtained by averaging the normalized adjustment and lack of problems score. A probabilistic lower bound to reliability of the composite in the population (ρ) is given by $\hat{\rho}_{.99} = .78$; that is, $\rho(\hat{\rho} \leq \rho) \geq .99$ (Woodward & Bentler, in press), indicating that the composite score possesses adequate internal consistency. This composite dependent variable differentiated the married from divorced groups quite well, $t(66) = 9.54, p < .001$.

Results

Evidence for the first hypothesis comes from within-group similarities between partners, with the homogamy hypothesis predicting greater initial similarity of partners among couples longitudinally successfully married than among those who become divorced or later separate.

In regard to this hypothesis, five of the background items (age, education, occupation, previous divorce, and previous children) had significantly positive husband/wife correlations for the married couples compared with four (age, education, parental divorce, and previous children) for the divorced couples. Table 2 shows these correlations in the top portion of columns 1 and 2; a one-tailed test in the hypothesized direction was used to assess significance. The third column in this table shows the Fisher r to z conversion for test for significant differences between correlations, also using a one-tailed test. Only the age correlation for the married group was significantly more positive than it was in the divorced group. Looking at the personality trait section of columns 1 and 2 of Table 2, it can be seen that there were 10 significant husband/wife correlations for the married couples, and there were 6 for the divorced couples, again using a one-tailed test. Four traits (ambition, liberalism, religious commitment, and travel interest) had significant positive correlations for both groups. The only substantial negative correlation was on stability for the divorced group: This seems to be an area in which a mismatch contributed to marital failure. Column 3 shows that three

* $p < .05$.** $p < .01$.*** $p < .001$.

correlations (art interest, attractiveness, and extraversion) were significantly more positive, using a one-tailed test, for the married, as compared with the divorced, group. Clothes consciousness, on the other hand, seems to be substantially contrary to the homogamy hypothesis, since a larger, positive correlation

was obtained for the divorced, compared with the still-married, group. As another way of looking at this issue, a sign test on the husband/wife correlations, compared across the married and divorced groups, showed that the still marrieds had more positive correlations than the divorced ($p < .05$, one-tailed test).

Turning next to mean differences rather than correlational similarities, the upper portion of column 4 in Table 2 shows that there were four background areas that were significantly different between husbands and wives for the married group; these differences were on age, height, weight, and occupation. Two-tailed *t* tests were used on these mean comparisons. A positive sign indicates the husband had the higher score, and a negative sign means that the wife had the higher score. Column 5 shows that for the divorced group three areas were significantly different; these were age, height, and weight. Looking

next at personality traits, column 4 shows that there were 16 significant mean differences between husbands and wives among the still-married group, whereas there were 6 significant mean differences for the divorced group, as can be seen in column 5. The groups were significantly different in regard to the number of trait differences when the results were considered statistically, $\chi^2(1) = 6.06$, $p < .025$.

We then looked at whether the magnitudes of the husband/wife discrepancies were statistically different between the married and divorced groups. Although none of the dis-

** $p < .01$.

*** $p < .001$.

crepancies were found to be significantly different, taken trait by trait, a sign test revealed that the husband/wife differences were significantly smaller overall for the divorced compared to the married group ($p < .05$, two-tailed). Combined with the correlational results, it seems that mean differentiation in personality between husbands and wives who are successfully married coexists with relative agreement correlationally, in self-perception.

Using tests appropriate for nominal data, the background items "race" and "religion" showed no significant husband/wife variation or difference between married and divorced groups.

Our second hypothesis, concerning peer/self congruity as a measure of accuracy of self-perception, is mildly supported by our findings. Referring to Table 3, columns 1 and 2 for males and 3 and 4 for females show that although there were more significantly non-zero peer/self correlations among both males and females of the married group than the divorced group, the difference in number was not significant for either males or females. Using again the Fisher r to z conversion, we find that thriftiness, for the males, and art interest, for the females, showed a significantly higher peer/self correlation within the married group as compared to the divorced group. (Although not related to marital differences, women showed a significantly larger number of nonzero peer/self correlations than did the males; apparently, there is greater peer/self agreement regarding the wife's personality than the husband's personality.) Turning to the mean scores, it was noted that the married males showed a significantly lower peer/self discrepancy (squared) on cheerfulness and law abidance, as compared to the divorced males, as can be seen in column 5 of Table 3. One trait, masculinity, showed analogous results for the females (column 6). Flexibility, for the males, turned out to be substantially contrary to our hypothesis. When the peer/self discrepancies (squared) on a given trait were averaged for the couple, cheerfulness and masculinity were significantly less discrepant in the married than in the divorced group (see Table 3, column 7). Flexibility, on the other hand, showed a sub-

stantially greater discrepancy for the married as compared with the divorced group, which is contrary to our hypothesis.

Our third hypothesis, concerning living together before marriage, was not supported by the data. For married couples, 24 lived together before marriage and 29 did not. For Divorced couples, 14 lived together before marriage and 10 did not, $\chi^2(1) = .66$, ns. In regard to other couple background characteristics, we found no significant differences between the divorced and still-married groups for the length of time they had known each other, been engaged, or lived together before marriage (if in fact they did). Although none of these mean differences was significant, the still-married couples tended to have known each other longer and to have been engaged longer than the divorced group. The opposite tendency was true for the duration of living together before marriage (if they did). The divorced group had lived together longer than the still marrieds. One other background question did turn out to be a statistically reliable predictor of marital success. The couples who have remained together more often had one or both partners previously widowed than did the couples who had divorced. In regard to the Sexual Behavior Inventory, there was no significant differentiation revealed between the married and divorced groups on this measure.

Our fourth hypothesis, concerning types of problems faced by divorced and married couples, shows some clear distinctions. Table 4 shows the mean values of the married and divorced groups for each problem area (in columns 1 and 2, respectively). Column 3 shows the t values for each problem area between the two groups. There were six areas—venereal disease, desire for children, drunkenness, gambling, male sent to jail, and in-laws—which were essentially no more of a problem for the divorced group than the married group. Twelve areas proved to be significantly greater problems for the divorced, compared to the married, group. These could be roughly considered to be interpersonal volitional areas in which conflict or disturbance can occur, for example, sex relations, lack of mutual affection, bickering, selfishness, and desire for independence. One area—

ill health—was found to be a significantly greater problem for the married than for the divorced groups. This is more of an involuntary problem and seems to have drawn the couples together.

The successful longitudinal prediction of marital success requires significant differentiation of means when comparing still-married and divorced groups. Columns 1 and 2 of Table 5 show the *t* values for these mean comparisons for the males and females, respectively. A positive sign indicates that the married group had the larger value, whereas a negative sign means the divorced group had the greater value. We used one-tailed tests of significance on the background items, since we had a priori expectations from previous research (e.g., Murstein & Glaudin, 1966), which we will address more fully in the Discussion section. The only significant difference on background item means between married and divorced males was on parental divorce.

The married males had fewer parental divorces than the divorced males. For females there were five significant mean differences. The married females were older, had higher educational and occupational levels, had more previous children, and had fewer parental divorces than the divorced females. Comparing mean scores on personality traits across the two groups, using a two-tailed test of significance, the following picture emerged: The married males showed significantly less extraversion, invulnerability, and orderliness compared with the divorced males. The married females showed significantly greater clothes consciousness and congeniality compared to the divorced females.

Next, we evaluated the longitudinal predictability of marital success with initial personality variables obtained at the time of marriage, variable by variable. The correlations between the composite dependent marital adjustment score and prior personality

scores were obtained separately for males and females (see columns 3 and 4 of Table 5). A two-tailed significance test was used. Among males, two significant correlations were found on extraversion and deliberateness. The more adjusted and happy the marriage, the more deliberate and less extraverted were the males. Among females, six significant correlations

were found for ambition, art interest, clothes consciousness, intelligence, objectivity, and stability. The higher the marital adjustment score, the more the females reported themselves to be clothes conscious, objective, and stable while reporting relatively less ambition, art interest, and intelligence. Again using the r to z conversion, column 5 shows the z

values when comparing the correlations of the males and females. Two correlations were significantly different between the males and the females. The males had negative correlations on extraversion and invulnerability, whereas the females had significantly different, positive correlations. The greater number of significant correlations on personality traits among females reflects the apparent greater predictability of marital success among women than men.

When the composite dependent variable was correlated with the background variables, by sex, there were two significant correlations for females and one for males. For the males, being older is predictive of marital adjustment, whereas for females, being older and having previous children are predictive of marital adjustment. There were no significant differences between males and females for any of the background correlations, using the r to z conversion.

Several longitudinal prediction equations involving linear combinations of predictor variables have been generated from our data, using as dependent variables (a) the com-

posite adjustment score and (b) being married versus divorced at follow-up. The most concise summarization of these results can be stated for the prediction equations using background and personality data from all male and female subjects, focusing on the continuous dependent variable (the composite score). A stepwise-regression procedure was used, which showed significant increments in prediction up to the point at which the procedure was terminated, due to a conservative judgment regarding stability of results on potential cross-validation. With 10 predictor variables the multiple correlation was .74, $F(10, 55) = 6.45$, $p < .001$. The beta weights for this equation are shown in the second column of Table 6, and the F test associated with this multiple regression model is given in the third row of the analysis of variance breakdown. All but one of the predictors contributed significantly ($p < .05$) to the multiple regression equation, whereas the weight of the remaining variable was 1.85-times its standard error.

To assess in finer detail the nature of the regression, we used a new regression model developed by Bentler and Woodward (Note 3; Woodward & Bentler, Note 4). This model can be written in the form $y = \beta^*Xt + X(\beta - \beta^*t) + e$, where y is the standardized dependent variable, X is the matrix of standardized predictor variables, and e is the residuals. The vector of the beta weights is the usual optimal vector of least-squares coefficients. The vector t is a sign vector with elements ± 1 , chosen to optimize prediction of y from X , and β^* is a weight associated with this regression. The Bentler-Woodward regression method in essence partitions the usual sum of squares due to regression into two additive components: one, associated with β^*Xt , and the second, associated with $X(\beta - \beta^*t)$. The first component is determined such that the sum of squares associated with that component is maximized; it represents the optimal prediction possible with weights β^*_i that are equal for all i predictors, except for sign. The second component assesses whether differential weighting contributes a significant increment to prediction beyond that possible with the signed, equal weights.

The Bentler-Woodward regression solu-

tion of Table 6 was obtained after the stepwise regression method yielded the 10 predictors shown in the table. It determined that the optimal sign weights for the regression were those given in the right-hand part of the table. In this case these signs are identical to those of the beta weights; this is not a necessary feature of the approach. The analysis of variance at the bottom of Table 6 shows that the null hypothesis that the contribution of the signed, equal weights to prediction is zero could be rejected at a high level of statistical significance ($p < .001$). On the other hand, the analysis of variance revealed that the contribution of variance revealed that the contribution of differential weighting, over and above the contribution of the signed, equal weights, was not statistically reliable. Thus, although the ordinary multiple regression procedure yielded a significant regression of criterion on predictor variables, the more fine-grained analysis reveals that virtually the only source of such prediction is associated with the signed, equal weights.

The proportions of variance associated with the Table 6 results mirror the statistical results. The correlation of the signed equal-weight composite with the criterion was .71, yielding an $R^2_{\beta^*} = .50$. The contribution of differential weighting was only $R^2_{\beta} - R^2_{\beta^*} = .04$. Of course, these two components of regression add to the total variance accounted for by the least-squares beta weights $R^2_{\beta} = .54$. As a consequence of these results, one would not expect the differential weights to cross-validate. Another way to assess the potential shrinkage due to using the highly tuned beta weights is to evaluate the adjusted R^2_{β} , which represents an unbiased estimator of the population squared multiple correlation (Olkin & Pratt, 1958). It is an adjustment of the R^2_{β} value using the number of independent variables and the sample size. Specifically, the equation we used was

$$\text{adjusted } R^2_{\beta} = 1 - \left(\frac{N-3}{N-k-1} \right) (1 - R^2_{\beta}) \\ - \left(\frac{N-3}{N-k-1} \right) \left(\frac{2}{N-k+1} \right) (1 - R^2_{\beta})^2,$$

where k equals the number of predictor variables in the equation and N equals the total

number of cases. Our adjusted $R^2_{\beta} = .46$, a value in the same range as $R^2_{\beta^*}$.

Turning now to the substantive meaning of the regression described in Table 6, the variables included in the regression were those obtained from women (presence of previous children, less ambition, objectivity, clothes consciousness, masculinity, and less intelligence) as well as from men (deliberateness, less orderliness, thriftiness, and less flexibility). In spite of the variable-by-variable results mentioned previously, the simultaneous approach indicates that self-reported personality variables contributed the major share to the longitudinal predictability of marital success, with background variables being barely represented in the multiple regression. (Only presence of previous children, among females, contributed significantly.) Furthermore, the majority of significant predictor variables came from the women's data, suggesting that variation in longitudinal marital success is a greater consequence of women's attributes than that of men. This effect was more dramatically observed in stepwise regression equations based on larger numbers of variables. For example, the 15-variable equation ($R = .80$) consisted of 10 variables from women and only 5 from men. Although the dimension of traditionality in sex role orientation (Ellis & Bentler, 1973) may be relevant to understanding these results (see Discussion), the differential prediction effect does not seem explainable.

One goal in constructing optimally weighted prediction equations is to find one that maximizes the amount of variance (R^2_{β}) accounted for by a small number of variables. Statistically, R^2_{β} can be decomposed into the sum of the products of the simple correlation coefficients and the beta weights for each variable in the equation. We arbitrarily set a minimum level of .03 for this product and located 15 variables from an equation based on the best 30 variables that met this criterion. These variables thus showed a minimally adequate beta weight in the set of all variables as well as a minimally adequate zero-order criterion correlation. Using these 15 variables in a stepwise regression manner led to the equation of Table 7. Only 12 variables became part of the final equation, since

3 of the 15 did not meet our minimum entry criterion in the stepwise inclusion ($F > 1.0$). Table 7 exhibits virtually the same pattern of results regarding the relative merits of various sets of weights as does Table 6. In this case,

$$R^2_{\beta^*} = .48, \quad R^2_{\beta} - R^2_{\beta^*} = .09, \quad R^2_{\beta} = .57, \\ \text{adjusted } R^2_{\beta} = .48.$$

Again, the signed, equal weights carry the lion's share of the total prediction, as well as the only statistically reliable effect.

To evaluate whether the stepwise regression procedure was somehow unfairly selecting from the pool of background or personality variables, or from variables associated with a given sex, we ran separate stepwise regression equations on the background variables and traits for the males and females. From each of these four equations, we selected the 2 best predicting variables according to an F test on the beta weights. Combining these 8 variables with the 10 in the first equation (Table 6) and the 12 in the second equation (Table 7), we arrived at a pool of 21 variables.

This pool was considered to adequately represent the background variables. A stepwise regression was run on this set of variables. The results are shown in Table 8. This equation uses 11 variables and was chosen since it maximized the overall F value associated with R^2_{β} . Perusing the substantive content, the sex difference is noted again, with the males being represented by 3 of the 11 variables and the females representing the majority by 8 of the variables. This result is not due to an initial bias in the pool of 21 variables, since they were fairly evenly divided by sex (10 males and 11 females). Turning finally to the quantitative results, we find that the analysis of variance mirrors the results of Tables 6 and 7. We have

$$R^2_{\beta^*} = .49, \quad R^2_{\beta} - R^2_{\beta^*} = .08, \quad R^2_{\beta} = .57, \\ \text{and adjusted } R^2_{\beta} = .49.$$

(It should be noted that the total degrees of freedom associated with Table 8 is two greater than in either Table 6 or Table 7. This is due to not having a complete data set on every

couple and does not reflect a numerical error.)

Although we did generate several equations using our dichotomous dependent variable (still married vs. divorced), we have chosen not to report these for several reasons. Most important was the consideration that the statistical assumptions underlying this type of dichotomous regression are less sound and proven than for a continuous dependent variable. This uncertainty and lack of soundness could create difficulty in cross-validating any dichotomously based equations. For example, a simple shift in the proportion of divorced couples in a given study would modify the optimal beta weights and the overall R^2 , due to the sensitivity of the regression to the mean of the dependent variable. This is why we have chosen to report only equations based on the continuous composite dependent variable.

Discussion

The present investigation has shown some clear longitudinal evidence for the homogamy hypothesis. Our results indicate that homogamy of personality traits between marital partners, assessed at the beginning of their marriage, is evidenced to a greater degree in marriages that turn out successfully than for marriages that terminate in separation or divorce. In other words, correlational similarity between marital partners, based on personality traits measured at the beginning of a marriage, was substantially higher for couples who remained together after 4 years than couples who decided to end their marriage within that period of time. This pattern was also found for background or demographic variables. Other researchers have found similar results cross-sectionally on personality traits (e.g., Cattell & Nesselroade, 1967; DeYoung & Fleischer, 1976; Pickford et al., 1966b). Using the Guilford-Zimmerman Temperament Survey, Pickford et al. (1966b) found four significantly positive husband/wife correlations on general activity, restraint, friendliness, and personal relations for their happily married group. Our significant finding on congeniality seems similar to theirs on friendliness for happily or still-married cou-

ples. They found no significantly positive correlations, but they did report one significantly negative correlation on emotional stability for couples on the verge of separation; our divorced sample had a similarly large negative correlation on stability. Cattell and Nesselroade (1967), using the 16 Personality Factor Questionnaire (16 PF), found four factors (Affectothymia, Surgency, Protension, and Self-Sufficiency) that were significantly more positively correlated between husbands and wives in stable marriages compared to couples in unstable marriages. Both Affectothymia and Surgency seem similar to our significantly different correlations on extraversion. DeYoung and Fleischer (1976) found all positive husband/wife correlations, using the 16 PF, with 10 (Affectothymia, Intelligence, Dominance, Surgency, Super Ego Strength, Autia, Radicalism, Self-Sufficiency, Self-Concept Control, and Ergic Tension) significantly so. They found these results in their one sample of couples who were still married and did not contrast them with a group experiencing marital disharmony or divorce.

This type of analysis does not directly address the need complementarity hypothesis (e.g., Meyer & Pepper, 1977; Murstein, 1961, 1967; Rosow, 1957; Winch, 1967), since the validity of inferring needs from personality traits is not adequately known. Nonetheless, one can consider many of our trait scales to be bipolar (e.g., extraversion: high score means very extraverted, a low score means very introverted), so that evidence for a complementary trait hypothesis can be examined. For the successfully married couples, no trait was found to have a significantly negative correlation between partners. If complementarity were an important influence for a successful marriage, some significant negative correlations should have been found in this group. The divorced group, on the other hand, had one substantial negative correlation on stability. Although we do not claim that these results disprove a complementary trait hypothesis, certainly there is no evidence favoring the concept. Yet, when we look at our simple prediction correlations by sex (traits predicting the composite dependent variable), we find two traits—

extraversion and invulnerability—that have significantly different effects for the males and the females. The happy and/or maritally adjusted males were relatively introverted and vulnerable, whereas the successfully married females were relatively extraverted and invulnerable. When comparing these two types of analyses—husband/wife correlations and simple predictive correlations between individual traits and the composite dependent measure—no clear support or refutation of the complementarity hypothesis seems evident. Thus, although we have found longitudinal support for the homogamy or correlational similarity hypothesis of spouse personality traits, we can say little regarding the complementarity (of traits) notion.

Some researchers (e.g., Singh et al., 1976) have found that significant mean differentiation of marital partners on personality traits occurs more often in successfully married couples than in those who divorce. These researchers implied that this finding is incompatible with correlational similarity between successfully married spouses. Our results do not provide longitudinal support for this cross-sectional finding. We found both significant mean differentiation as well as correlational similarity on personality traits between partners within the still-married group. In addition, we found greater mean differences among the successfully married than the divorced. In other words, correlational similarity does not necessarily imply equality of trait levels; it only indicates that the traits are related in a linear manner. Apparently, correlational similarity and mean differentiation between marital partners are both conducive to subsequent marital happiness and success. How this finding is reflected in spouses' behavior toward each other and how it might contribute to marital satisfaction is unclear. Further theory development and research needs to be done to integrate and thoroughly understand this finding.

Our hypothesis concerning the effect of self-perception accuracy, as revealed by peer/self rating comparisons, was only mildly supported by our data. We speculated that the more similar peer- and self-ratings were before marriage, the more accurately that spouse would self-perceive in the marriage.

He or she should then face a marriage relationship more adaptively, resulting in greater adjustment, happiness, and ultimately success in marriage. Weigel, Weigel, and Richardson (1973), addressing somewhat similar issues, found no significant results, whereas Murstein and Beck (1972) found some general support for this idea. Although our findings were not strong, many were in the direction hypothesized, and some significantly so. Some results found contrary to this hypothesis have been previously noted. Perhaps if the proportion of our sample that did have peer assessments of their personalities had been larger, more definitive results might have been found. Of course, it is also possible that accuracy in interpersonal and self-perception may generate a more rapid separation if the marriage is in actual trouble, or perhaps the effect of accuracy depends on the particular traits involved. We have not as yet developed an adequate theory in this regard.

Our hypothesis concerning living together before marriage was not supported by the data. This is a somewhat discouraging finding in light of the currently growing movement toward trial or premarriages. The effect of living together would seem to merit further study beyond our reported results to determine if there are any specific variables in the couple that are important to making this experience a helpful or hindering influence on any potential subsequent marriage.

An analysis of problems faced by married couples compared to divorced couples revealed some clear distinctions. "Ill health" was the only significantly greater problem for the still marrieds and seemed to be an involuntary problem that helped draw the couple together. Several areas represented a significantly greater problem for the divorced group and could be roughly classified as volitional/relational problems. It is interesting to note that although "drug abuse" was a significantly greater problem for the divorced group, "drunkenness" was in absolute terms a greater problem for both groups than drug abuse. Thus, even though drug abuse has recently received much public attention, alcohol appears to be the greater problem during the first few years of marriage for both married and divorced couples.

In regard to the longitudinal predictability of marital success, we found seven background or trait variables that significantly differentiated the married females from the divorced females. Four background or trait variables significantly differentiated married from divorced males. Several of the background variable differences have been found by other investigators. The age relationship was found by the U.S. Bureau of the Census (1973), Luckey (1966), and Landis (1956, 1963). The educational difference was also noted by Murstein and Glaudin (1966), whereas Landis (1956, 1963) found results opposite to ours on education and occupational levels, probably because differing methods were used to define experimental groups. Several other studies (e.g., Pope & Mueller, 1976; Renne, 1971) have reported results similar to ours on parents' divorce. On the basis of previous research, we had expected that the married group would have had fewer previous divorces than the divorced group, but this effect was not found in our data. It indicates, somewhat happily, that previously divorced individuals are not at a special risk in future marriage.

We found three significant mean differences on traits between the married and divorced groups for the males and two for the females. Previous cross-sectional research (e.g., Cattell & Nesselroade, 1967; Pickford et al., 1966a; Singh et al., 1976) has found personality differences between married and divorced groups. Using the Guilford-Zimmerman Temperament Survey, Pickford et al. (1966a) found one significant difference between happily married males and males who were in marriages that were on the verge of divorce. This trait was personal relations, which may be related to our finding that males differed on extraversion. No significant differences were found between the groups for females in the Pickford et al. (1966a) study. Cattell and Nesselroade (1967), using the 16 PF, found five traits (Intelligence, Dominance, Protension, Shrewdness, and Self-Concept Control) that significantly differentiated stable from unstable marriages on husband/wife averages. Also using the 16 PF, Singh et al. (1976) found three traits (Premsia, Timidity, and Ergic Tension) that signifi-

cantly differentiated males in happy marriages from males in marital disharmony. Our significant differences for males on extraversion and invulnerability seem to coincide with their findings on Timidity and Premsia, respectively. These researchers found no significant differences between their sample groups for the females. We were not able to replicate the finding of Reevey (1963) regarding greater previous sexual experience in persons with an unfavorable marital happiness prediction; such sexual experience was unrelated to actual marital success or failure in our sample.

There were three significant simple predictive correlations between the composite dependent score and background or trait variables for the males. In contrast, there were eight significant correlations for the females. It could be argued that rather than reveal a linear trend, trait levels could relate to marital adjustment in some curvilinear fashion. For example, perhaps intermediate levels of a particular trait are more conducive to marital happiness than extremes in either direction. Although this is a possibility, we have chosen to look for linear relationships, since experience has shown little empirical support for curvilinear relationships on cross-validation (e.g., Wiggins, 1973).

For both mean differentiation between married and divorced groups as well as simple predictive correlations, the females showed the largest number of statistically significant results, indicating that the woman has greater predictive influence on the outcome of a marriage than does the man in the marital dyad. This sex difference was also found longitudinally for dating couples by Hill et al. (1976) and cross-sectionally by Murstein and Glaudin (1966). In our study, these trait differences between groups cannot be attributed to interactions between spouses. Rather, they precede marital interaction and apparently have some bearing on the subsequent outcome and quality of a marriage.

In her review of the marital adjustment literature, Laws (1971) showed that women adjust better to their husbands, given the traditional definition of roles in marital relationships. Similarly, in our study, women who rated their own ambition, intelligence, and

interest in art as being low also tended to be more satisfied 4 years later, and women who had children from a previous marriage also had greater solace in their new marriage at follow-up. Certain personality traits and some background items for women, then, seem to be quite consistent with a traditional definition of marital adjustment in society as it is today. Cross-validation in a population or society that has different values or role definitions may be less than fully confirmatory. For instance, if traditional female roles, the value of heterosexual relationships, and definitions of marital happiness change or become altered in some manner—as the feminist movement might desire—our findings on specific variables may not be replicated within this new cultural framework. It remains possible, however, that our general findings concerning homogamy, self-perception, problem areas, and so forth, will not be severely affected by a modification in society. Furthermore, certain results (such as on extraversion and invulnerability, which showed significantly different associations with marital adjustment by sex) indicate that nontraditionality may yield greater marital adjustment. Thus, the concept of sex role traditionality (e.g., Ellis & Bentler, 1973) cannot explain all the major results.

In choosing to look at personality trait variables for longitudinal prediction of the quality of marital success or failure, we had made the unproven—albeit reasonable—assumption that these types of variables will be more powerful predictors than simple background or demographic characteristics. To test this idea, we chose the two best predicting traits for the males and then the females. We then regressed these four traits on the composite dependent variable. This equation had an R of .54, $F(4, 63) = 6.58$, $p < .001$. We then chose the two best predicting background variables for the males and then the females. We entered these four variables into a prediction equation and obtained a multiple correlation of .42, $F(4, 63) = 3.39$, $p < .025$. The first equation accounted for 29% of the criterion variance, and the latter equation accounted for 18% of the variance. It seems clear when comparing these two equations that the traits have a much greater longi-

tudinal predictive effect than do the background/demographic variables.

Previous prediction equation research (Karlsson, 1951; Kelly, 1939; Locke & Karlsson, 1952; Terman & Oden, 1947) have found multiple correlations ranging from .32 to .59 using personality and/or background variables. Our equations seem to be a fair improvement over these, with multiple correlations in the .75 range. Unfortunately, our sample size was too small to cross-validate these equations, and thus this task must be left for later research. It should be noted that as a rule of thumb, for beta weights to be reliable estimates of the population, there should be about 30 cases for each predictor variable. Since our sample size does not permit this, our betas are liable to fluctuate to some extent on replication. To assess whether the optimal beta weights indeed represent some important feature of the data rather than accidental noise, we calculated the unbiased estimator of the population squared multiple correlation. This indicated that about 8%–10% of the predictive variance was due to overfitting in the sample. In view of our use of stepwise regression, which also capitalizes on chance to some extent, we would expect the population R of about .69 to be an upper-bound value rather than a true unbiased estimator that equally overshoots and undershoots the true value in its estimates. A completely different coefficient is given by the sample cross-validity correlation, which estimates the effect of using the sample regression equation in the population. Using the conservative Darlington (1968) coefficient, we obtained predicted correlations of .59, .58, and .61, somewhat below the unbiased estimates for Tables 6, 7, and 8 but still substantial in magnitude. We also used a novel regression method from Bentler and Woodward (Note 3), which determines the optimal prediction possible by using signed, equal weights rather than beta weights. This procedure found that the only significant contribution to prediction was being made by the signed, equal weights, and that any further contribution due to differential weighting simply represented statistical noise. Consequently, we would urge the use of signed weights rather than beta weights in future

replications, since these signs appear to carry all the reliable predictive information. With such weights, one obtains $R \cong .70$, still a substantial improvement over previous research. Of course, replication of the signs in new samples is a clear task for future research.

Our emphasis on predicting marital success or failure from factors assessed at the beginning of a marriage presupposes that marriage may somehow alter the personality traits of each partner. Further study needs to be done regarding how such traits are changed, if in fact they are. Does a successful marriage alter one's personality traits in a given direction—for example, in a "regression effect" toward the mean of both partners—and does the change depend on the success of the marriage? Are traits affected differentially by various marital experiences?

The interaction of two people in that uniquely intimate and intensive situation called marriage is an immensely complicated process that draws on many factors of each member's background and personality, as well as more situational characteristics. A marriage is the result of what each partner brings to the marriage and what they make of it, once together. We have focused on what each partner has brought to the marriage in order to understand the variations that seem to limit the best that individuals can subsequently make of their marriage.

Sum of MMPI Scales *F*, 4, and 9 as a Measure of Aggression

Monroe M. Lefkowitz

New York State Department of Mental Hygiene
Albany, New York

Leonard D. Eron

University of Illinois at Chicago Circle

The relationship between scores on the Minnesota Multiphasic Personality Inventory and both concurrent and prior aggression was examined for a sample of 426 19-year-olds from the general population. Aggression was measured through peer nominations obtained concurrently and 10 years earlier. Correlation and regression analysis indicated that the sum of *T* scores for Scales *F*, 4, and 9 was a valid measure of aggression. The composite was also shown to have a higher reliability than its component scales. Using an additional 283 subjects from delinquent populations, it was demonstrated that the composite was an excellent discriminator between delinquent and general populations of males and females even when intelligence and social status were controlled.

Elevation of the *T* scores on both Scales 4 and 9 of the Minnesota Multiphasic Personality Inventory (MMPI) has been thought to form the profile characteristic of the male juvenile delinquent (Dahlstrom & Welsh, 1960; Dahlstrom, Welsh, & Dahlstrom, 1972; Hathaway & Monachesi, 1953). Scale 4 (Psychopathic Deviate) by itself has been used to measure levels of social deviance or antisocial behavior (Elion & Megargee, 1975; Hathaway & Monachesi, 1953; Megargee & Mendelsohn, 1962). Dahlstrom et al. (1972) noted that marked elevations on Scale 4 can be observed in prison groups. These authors also noted that Scale 9 (Hypomania) appears to energize the pattern related to Scale 4. Scale 9 was viewed by Hathaway and Monachesi (1953) as an exciter that in combination with

Scale 4 produces rebellious and excitable behavior in high-delinquent children. A later analysis of their data (Monachesi & Hathaway, 1969) showed that the highest rates of delinquency for both boys and girls were associated with deviance in MMPI Scales 4, 8, and 9.

In a study of juvenile delinquents who succeeded or failed in adjustment to institutionalization, Lefkowitz (1966) found that the mean score on Scale 9 was significantly higher for the failures. Similarly, in a follow-up study of paroled prisoners whose postrelease behavior was classified as acceptable or unacceptable, the MMPI 49 code type was heavily represented among the unacceptable group (Jacobson & Wirt, 1969). Butcher (1965) found that highly aggressive boys (based on peer nominations) had significant elevations on Scales 4 and 9. These boys responded in a rebellious and excitable manner in interpersonal situations, whereas the low-aggressive boys tended to internalize their conflicts, which were then manifested in hypochondriacal symptoms and withdrawal.

There has been a proliferation of attempts to validate not only certain of the clinical scales as aggression measures (see, e.g., Megargee & Mendelsohn, 1962; Shipman, 1965) but also a number of special scales developed from the MMPI. At this writing,

This study was supported by Grant M1726 from the National Institute of Mental Health, by Contract HSM 42-70-6 from the Surgeon General's Scientific Advisory Committee on Television and Social Behavior, and by the New York State Department of Mental Hygiene. The data analysis was performed with the assistance of the computation center of the University of Illinois at Chicago Circle. For Part 1 of this study, Leopold Walder was a co-investigator.

as many as 25 scales of the MMPI have been proposed as measures of hostility or aggression (Deiker, 1974). Thus, the present study is an attempt to simplify this area of measurement by providing a reliable and valid single score of aggressive behavior obtained by summing the *T* scores of a few common clinical scales. The virtue of a single score over a profile of scale scores is that the former is readily usable as a continuous variable, whereas the latter is a dichotomous variable and therefore in the main limited to frequency analysis.

A two-step procedure was followed in this study. First, using a sample of subjects from a general population, we attempted to identify a valid and reliable composite of *T* scores for measuring aggression. Then using a sample of subjects from a delinquent population, we attempted to validate the composite as a discriminator of delinquent adolescents.

Study 1

Method

Subjects. The subjects were part of a larger longitudinal research project on aggressive behavior reported elsewhere (Eron, Huesmann, Lefkowitz, & Walder, 1972; Lefkowitz, Eron, Walder, & Huesmann, 1977). In the first wave, data were gathered during 1959-1960 from the entire 3rd-grade population of 875 boys and girls residing in a semirural county in New York State. Ten years later in the second wave, termed the "13th grade," data were collected from 426 of these subjects (211 boys and 215 girls who could be located at that time; Lefkowitz et al., 1977). In the 3rd and 13th grades, the modal ages of this sample of 426 were 8 and 19 years, respectively. The mean IQ of this sample in the 3rd grade was 107.10 ± 13.66 . Based on fathers' occupation, the sample can be described as predominantly middle class.

Procedure. In the 3rd and 13th grades, aggression scores were obtained by a peer nomination questionnaire comprised of items describing aggression behavior. For example, each subject was asked to name anyone in the classroom "Who starts a fight over nothing?" The peer nomination technique also included items intended to measure aggression avoidance; for example, "Who will never fight even when picked on?" The reliability ($r > .85$) and validity of this aggression measure and its the procedures for administration have been discussed elsewhere (Butcher, 1965; Eron, Walder, & Lefkowitz, 1971; Walder, Abelson, Eron, Banta, & Laulicht, 1961). In the 3rd grade the peer nomination technique, including 10 aggression items, was administered to classroom groups. In the 13th grade the technique, using 9 of the 10 aggression items from the 3rd grade, was administered individually to subjects as part of a larger 2-hour interview procedure. At the time of the 3rd grade interview, IQ (Sullivan, Clark, & Tiegs, 1957) and father's occupational status (U.S. Bureau of Census, 1960) were recorded for most subjects. During the 13th grade interview, subjects also completed self-report inventories on aggressive behavior and were administered the MMPI. The *K*-corrected *T* scores on the MMPI were used as the potential predictors of aggression in this study. The self-report measure of aggression, termed *total aggressive environment*, was comprised of 43 items divided into five subscales: (a) respondent as a victim of aggression, (b) respondent as a witness of aggression, (c) respondent's aggressive habits, (d) respondent's antisocial behavior, and (e) respondent's aggressive feelings. The exact composition of this scale and the procedures used to administer all of the 13th grade measures have been reported elsewhere (Lefkowitz et al., 1977).

Results

The intercorrelations between the various measures of aggression are shown in Table 1 for all 426 subjects. Since 13th grade peer-rated aggression (Peer Agg 13) correlated well with all the other measures and was measured at the same time that the MMPI was admin-

istered, it was decided to use it as the primary criterion measure. Since sex was significantly related to aggression, all further analysis were done separately for males and females.

Table 2 shows the correlations between Peer Agg 13 and each of the MMPI scales as well as the results of a multiple regression analysis predicting Peer Agg 13 from the MMPI scales. For males, as expected, Scales 4 and 9 were highly significant correlates of aggression, but Scale *F* was also highly correlated. Scale 8 correlated less highly though significantly. For females, the two best univariate predictors were Scale 4 and the *F* scale. Scales 5, 9, and 10 also were significantly correlated with aggressiveness but not as highly. Since the *T* scores for Scales 4, 7, 8, and 9 were *K* corrected and since *K* scores were slightly negatively correlated with aggressiveness, the observed correlations between aggressiveness and 4, 7, 8, and 9 may have been slightly reduced by the *K* correction. However, the reduction could not be significant considering the small size of the correlation between *K* and Peer Agg 13.

The multiple regression analysis shows the

best weighted composite of the *T* scores for measuring aggression.¹ As expected, the regression coefficients reveal that Scale 4 was the most important predictor of aggression across sexes. Surprisingly, however, Scale *F* was as important a predictor for females and equal with Scales 5 and 9 in predicting aggression in males. Scale 5 relates negatively to aggression in males and positively in females, indicating the relation between aggression and sex role behaviors. Scale 9 made an important contribution for males but not for females, for whom Scale 10 appeared as an inverse predictor.

Discussion

From these results it appears that a composite to be used as a general measure of

¹ The raw regression coefficients are presented because the objective is to develop a predictive composite. Even though the intercorrelations between the MMPI scales are mostly significant, they only range from $-.32$ to $.52$ for the significant scales in the equation, so multicollinearity should not be a serious problem.

aggression across sexes without contamination by sexual stereotyping should be composed of Scales *F* and 4 and either Scale 9 or scale 10. Of course, a weighted linear composite involving every scale would have the highest correlation with aggression. However, a measure consisting of the sum of only two or three scales has the advantage of simplicity and ease of administration. Furthermore, as Wainer (1976) and others have argued, the simple sum of significant predictor variables is often almost as good a predictor in the population as the entire multiple regression equation.

Scale 5, although a significant predictor, is not a desirable variable to include in a general measure of aggression, because it represents that component of aggression associated with sexual stereotyping. Since it was included in the regression equation, however, the effects of sexual stereotyping have been partially controlled in determining the other significant predictors.

On a priori grounds, Scale 9 would seem to be a more appropriate element to include in a measure of aggression than Scale 10. It is intended to measure a propensity for manic behavior, so it certainly has face validity as a component of aggression. Furthermore, as reported in the Introduction, Scale 9 has been found to be significantly higher in several high-aggressive, albeit male, populations. On the other hand, Scale 10 has to our knowledge never been proposed as a discriminator of delinquents. In addition, the utility of Scale 10 in this study could possibly be an artifact of the peer nomination procedure. A female scoring high on Scale 10 is scoring high on social introversion. Therefore, she might be less likely to be nominated by her peers on any scale resulting in negative correlations. The available data are consistent with this interpretation. Even though Scale 10 correlated negatively with peer-rated aggression for females ($r = -.15$, $p < .03$), it did not correlate significantly with self-rated aggression ($r = .04$), though one would usually expect a higher correlation between two self-ratings. Also, peer-rated popularity, which correlated negatively with peer-rated aggression ($r = -.28$, $p < .001$), had exactly the same correlation with Scale 10 ($r = -.15$) as did peer-rated aggression. Thus, it seems that

Scale 10 is measuring a component of peer rating more than aggression. Scale 9, on the other hand, correlated more significantly with self-rated aggression for girls ($r = .34$, $p < .001$) than with peer-rated aggression ($r = .15$, $p < .03$). Therefore, a composite measure of aggression was constructed consisting of the sum of Scales *F*, 4, and 9.

Table 3 displays the correlations between this composite measure of aggression and each of the other variables measuring aggression. It also contains the correlations between the aggression measures and the individual scales. One can see that for males the sum of Scales *F*, 4, and 9 is a valid measure of concurrent aggression and is significantly related to the subject's aggression to years earlier. The composite correlated more strongly with every measure than any of its components or *F* + 4. For females, the composite also correlated significantly with every measure of concurrent aggression, though less strongly than for males. Scale 4 alone and *F* + 4 are just as strongly or slightly more strongly related to peer ratings than the full composite, but the full composite did better on the other measures. The composite also significantly correlated with aggression 10 years earlier.

Reliability

The reliability of any linear combination of variables can be computed from its variance and the variances and reliabilities of its components. For the current sample, however, MMPI item scores were not available to us, so reliability data from comparable samples had to be used. The largest study of reliability in a college-age population of normals appears to have been conducted by Mauger in 1972 (cited in Dahlstrom et al., 1972). Test-retest correlations were computed for 490 subjects over an 8-month lag. The average correlations of males and females were .56 on Scale *F*, .57 on Scale 4, and .62 on Scale 9. These relatively long-term stability coefficients can be viewed as lower bounds on internal consistency reliabilities (i.e., coefficient alpha). Dahlstrom et al. (1972) did not report any studies involving a substantial number of normal college-age subjects for which coefficient alpha was calculated, so these stability coefficients

Table 4

Means for F + 4 + 9 as a Function of Sex and Delinquency

Population	Males	Females	Total
General	183.3	174.6	178.9
<i>n</i>	210	215	
Delinquent	217.4	237.7	227.2
<i>n</i>	147	136	
Total	197.3	199.0	198.2

will have to serve as our conservative estimates of reliabilities. We can now show that even assuming such conservative estimates, the reliability of *F* + 4 + 9 is acceptable.

From Nunnally (1967, p. 229), we can write:

Let

$$y = \text{MMPI}_F + \text{MMPI}_4 + \text{MMPI}_9$$

$$r_{yy} =$$

$$1 - \frac{(\sigma_F^2 + \sigma_4^2 + \sigma_9^2) - r_{FF}\sigma_F^2 - r_{44}\sigma_4^2 - r_{99}\sigma_9^2}{\sigma_y^2}$$

Using our sample of 427 subjects to estimate the standard deviations gives

$$\sigma_y = 26.52 \quad \sigma_F = 10.82 \quad \sigma_4 = 11.15 \quad \sigma_9 = 11.50,$$

and using Mauger's stability coefficients as conservative estimates of reliability gives

$$r_{FF} = .56, \quad r_{44} = .57, \quad \text{and} \quad r_{99} = .62.$$

Therefore,

$$r_{yy} = 1 - \frac{155.23}{703.31} = .78.$$

Thus the reliability of *F* + 4 + 9 is substantially higher than the reliabilities of its components and sufficient for its use as a measure of aggression. Furthermore, using less conservative estimates of the reliabilities of the scales based on 1-week stabilities (Dahlstrom et al., 1972), the reliability of *F* + 4 + 9 is almost .87.

Study 2

To further validate *F* + 4 + 9 as a measure of aggression, a second analysis was undertaken to compare a sample from a known population of delinquents with the previously studied sample from a normal population.

Table 5

Analysis of Covariance for $F + 4 + 9$ as a Function of Sex and Delinquency

Source	df	SS	MS	F
Covariates				
IQ	1	157,298.44	157,298.44	218.27*
Father's occupation	1	13,772.81	13,772.81	19.11*
Effects				
Sex (A)	1	10,496.69	10,496.69	14.57*
Population (B) ^a	1	153,635.63	153,635.63	213.19*
A \times B	1	17,628.37	17,628.37	24.46*
Residual	621	447,522.25	720.65	
Total	626	800,354.19		

Note. The total sample size for the analysis of covariance was only 627 because IQ or father's occupation was missing for 81 subjects.

^a Delinquent versus general.

* $p < .001$.

Method

Subjects. The delinquency sample consisted of 136 females institutionalized at a facility of the New York State Division for Youth and 147 males from a privately operated institution for delinquent boys in New York.² All subjects had been sent to the institutions by family and children's courts. The subjects ranged in age from 12.9 to 17.1, with a median of 14.9. The mean IQ for girls was only 77.3 but was 100.3 for boys. The entire population of the institutions minus a few subjects for whom usable data could not be obtained constituted the sample. The offenses committed by the delinquents ran the gamut from incorrigibility, shoplifting, petty larceny, and prostitution to car theft, breaking and entering, and assault.

Procedure. Form R of the MMPI was group administered to 3-5 subjects at a time. The 399 items were read aloud twice on a tape while the subjects, closely monitored, read along silently in their booklets. The IQs and fathers' occupations were obtained from the subjects' case histories.

Results

The means and analysis of covariance shown in Tables 4 and 5 indicate that $F + 4 + 9$ is an excellent discriminator between populations known to vary in their levels of aggression. The analysis of covariance was performed in a hierarchical manner, so the F value for delinquent versus nondelinquent populations, $F(1, 621) = 244.1$, $p < .001$, represents the discriminative strength of $F + 4 + 9$ after the effects of IQ, father's occupation, and sex have been partialled out. Since the standard deviation of the composite was about 25, the table of means indicates that delinquent boys scored about $1\frac{1}{2}$ standard deviations higher

than normals, and delinquent girls scored about $2\frac{1}{2}$ standard deviations higher. This greater difference for females is reflected in the significant Sex \times Population interaction $F(1, 621) = 25.83$, $p < .001$. Although males scored higher than females on $F + 4 + 9$ in the normal population, $t(423) = 3.42$, $p < .001$, females scored higher in the delinquent population, $t(281) = 5.98$, $p < .001$.

Discussion

These results provide construct validity for the sum of MMPI Scales F , 4, and 9 as a measure of aggression. The sum of these scales was an excellent discriminator between delinquents high in aggression and youth from a normal population even when IQ and social class were controlled. Furthermore, as one would predict for a measure of aggression, nondelinquent males scored significantly higher on $F + 4 + 9$ than nondelinquent females. Within the delinquent group, however, females, contrary to the hypothesis, scored significantly higher than males. Speculatively, this unexpected result of higher scores for delinquent females than delinquent males on this MMPI measure may be due to an artifact of selection. Traditionally, females have encountered far fewer difficulties with law-enforcing agencies

² The authors wish to express their thanks for the cooperation of the staffs of the Hudson School for Girls and the Berkshire Farm Institute for Training and Research.

and/or have been treated more leniently by these agencies than males, particularly juveniles (Monachesi & Hathaway, 1969). Thus, in order for a female to be considered delinquent and institutionalized, the level of antisocial behavior may have to be excessive as compared to males. Consequently, the present group of institutionalized delinquent females may be unrepresentative of delinquent females generally, in that their level of aggressiveness may be inordinately high. The unusually low mean IQ for the female delinquents supports this interpretation. If this post hoc hypothesis is valid, this MMPI measure should be able to discriminate among degrees of delinquency in a population of delinquent females.

Although the normals in the present study were approximately 5 years older than the delinquents, it is unlikely that this age difference affected the results. Hathaway and Monachesi (1963) provided MMPI norms for 4,944 boys and 5,207 girls in the ninth grade whose average ages, respectively, were 15.1 and 14.9 years. The sum of the *T* scores on Scales *F*, 4, and 9 were 176.3 for boys and 170.4 for girls. These values are markedly below those of delinquents of the same age (as shown in Table 4) but approximately the same as those of the normal subjects in the present study.

Summary

The results of the present study indicate that the sum of the *T* scores on MMPI Scales *F*, 4, and 9 serves as a reliable and valid unitary measure of aggression. Highly significant correlations obtained between *F* + 4 + 9 and both peer-rating and self-rating of aggression. Added strength is lent to the validity by the fact that scores on the measure related back 10 years in time to nominations on aggressive behavior that the subjects received from their peers in a classroom setting. Moreover, as evidenced by the multiple regression analysis, the composite is valid for both males and females and is not simply a sex-typing measure. In general, the sum of these scales appeared more valid than any of its components. Other support for the validity of this MMPI measure was derived from its ability

to distinguish between delinquent and non-delinquent populations known to differ in aggressiveness. Finally, *F* + 4 + 9 was shown to have a reliability greater than that of any of its components.

Although the intent was to validate this measure on a noninstitutionalized population of normal subjects, the fact that the measure discriminates so well between institutionalized and noninstitutionalized populations suggests that it may also be useful in criminal justice settings in which the MMPI is so widely used. The ease with which this measure is obtained from the MMPI makes it a potentially useful tool for screening and perhaps program placement in such settings. Also, the measure meets the demand for a valid paper-and-pencil measure of aggressive behavior for research with normal subjects.

A Longitudinal Study of Coping Styles in Self-Defining and Socially Defined Women

Abigail J. Stewart
Boston University

In a longitudinal study of 51 female college graduates, self-definition as measured by freshman-year Thematic Apperception Tests predicted several aspects of problem-solving and coping behavior 14 years later. Those women who viewed themselves, their world, and their own personal problems in ways that facilitated effective coping scored higher in self-definition. The women who took instrumental actions to solve their problems, rather than taking noninstrumental actions or remaining passive, also scored higher in self-definition. Theoretical and practical implications of these findings are discussed.

Self-definition and social definition were proposed by Stewart and Winter (1974) as two contrasting patterns of organization of experience that are important in understanding intrasex differences in women.¹ Stewart and Winter began by identifying two different styles of storytelling that characterized Thematic Apperception Test (TAT) stories of career-oriented and non-career-oriented female college students. The stories written by the career-oriented women were marked by a clear, causally organized plot and instrumentally active and effective characters. The stories written by the non-career-oriented women were characterized by inactivity or ineffective activity on the part of characters, and by an absence of intelligible causal ordering of the plot.²

Stewart and Winter argued that these two styles of storytelling reflected an underlying pervasive personality characteristic. They presented evidence that the women who told stories of rationally caused events created by

effective actors were (a) relatively indifferent to sex role norms (and perhaps to norms associated with other roles); (b) capable of emotional "distance" and objectivity in the context of a small number of intense, personal relationships; (c) active and interested in broad social movements and issues; and (d) capable of vigorous instrumental activity.

The women who told stories in which events were chaotic and in which characters were helpless (a) behaved in accord with sex role norms; (b) showed rather superficial emotional attachments to a large number of people, with little capacity for analytic "distance"; (c) were deeply preoccupied with their own emotional and social lives; and (d) showed a greater inclination toward expressive rather than instrumental activity. The initial research reported by Stewart and Winter (1974), then, indicated that these two patterns of thought (self- and social definition) were coherently reflected in two similar patterns of ordinary behavior in female college students. In later research, Stewart (1975) showed that self-definition predicted career and work activities as well as certain marital and family patterns in adult women. Winter, Stewart, and Mc-

The author wishes to thank David C. McClelland and David G. Winter for their advice and help with this research, which was partially supported by a fellowship from the Peter B. Livingston Foundation and a grant from the Fund for the Improvement of Post-Secondary Education.

Requests for reprints should be sent to Abigail Stewart, Department of Psychology, Boston University, 64 Cummington Street, Boston, Massachusetts 02215.

¹ Later research (see Winter, Stewart, & McClelland, 1977) has indicated that it may also be relevant in studying men.

² Validation research and the psychometric properties of the measure are discussed in detail in Stewart and Winter (1974).

Clelland (1977) also showed that self-definition was associated with nontraditional marriage patterns in a longitudinal study of adult men.

No research, however, has explored the possibility that the patterns associated with self- and social definitions might extend to the domain of adult behavior in response to life stress. Nevertheless, the presumably general and stable tendencies to organize experience identified in Stewart and Winter's (1974) original study should have important consequences for an individual's approach to solving a personal problem. A great deal of theory and laboratory evidence suggests that individuals' attributions about the causes of events (see de Charms, 1968; Kelley, 1972) and their feelings of personal control over events (see Rotter, 1966; Seligman, 1975) have important consequences both for their acts and their emotional states. Self- and social definition are alternative patterns of organization of experience that do not involve *conscious beliefs* (as "locus of control" does) but rather *implicit beliefs*. Moreover, the two patterns simultaneously reveal implicit beliefs about the causal organization of external reality and one's own capacity for causal agency (see, e.g., de Charms, 1968) rather than being restricted to one or the other. It is assumed here that stable patterns of thought (implicit belief systems) about one's capacity to influence events, and about the predictability and meaningfulness of events in general, will affect individuals' styles of responding to personal life events.

Thus, if a woman sees the world as a systematic environment in which events have identifiable causes, it seems reasonable that she would seek out the causes of her problems. If, however, a woman sees the world as an essentially random environment in which events lack intelligible causes, she will waste no time in fruitless searches for nonexistent explanations for her problems. Also, a woman who sees the individual as a locus of effective voluntary action will take action to solve her problems, whereas a woman who sees individual action as futile and pointless may simply wait for this, too, to "pass."

On the other hand, the link between world view and coping style may not be so close. A socially defined woman could "typically"

see the world as chaotic and herself as helpless, but when faced with real problems she might seek out the causes of the problems and rational action to solve them. Alternatively, a self-defining woman who "normally" sees the world as orderly and herself as effective might be overwhelmed and paralyzed by a personal difficulty. One test of an individual's commitment to a world view, then, may be the extent to which that world view is retained in the face of calamity.

The purpose of this study was to test the general hypothesis that self-defining and socially defined women would indeed respond to personal life stresses differently and in ways that are consistent with their respective world views. An adequate test of this hypothesis offers the possibility of extending the construct validity of self-definition and at the same time determining whether alternative coping styles are grounded in characteristic constructions of social reality.

Hypotheses

The first hypothesis investigated in this study is that self-defining women will be more likely than socially defined women to interpret their own personal problems as existing outside of themselves. That is, they will tend to see a problem (regardless of its content) as located in the environment, rather than within their own personality. However, the second hypothesis is that self-defining women will be more likely than socially defined women to interpret the *solution* to their problems as located within themselves. That is, they will see the *problem* as external to themselves, but the *solution* will be seen as internal; in this way, it is presumed, they may reasonably plan to initiate action to solve the problem. If the problem seems internal, or if the solution of the problem seems external, it may make little sense to take action. Only if the problem appears to be external, but the solution to the problem appears to be within one's control, is it reasonable for an individual to take action to solve it.

In addition, it is hypothesized that self-defining women will be better able than socially defined women to clearly articulate the *nature* of their problems and their solutions,

and to identify the causes of these problems. That is, the stable tendency to see the world as rational and causally organized will be reflected in a tendency to see a particular problem as the result of a number of factors that are intelligible and identifiable.

It is further hypothesized that self-defining women will be more likely to present their problems in a broad social context. They will be more likely to experience their problems as involving a wider network of social relationships (e.g., colleagues in work and voluntary settings, the wider society), whereas socially defined women will be inclined to define their problems as located within their personal domestic context (i.e., the home, marriage, or family).

Finally, it is hypothesized that self-defining women will be more likely than socially defined women to make instrumental responses to their problems, and that socially defined women will be more likely to make either noninstrumental responses or no active responses at all to their problems. Thus, overall, it is hypothesized that an individual's particular interpretation of and response to a particular life problem may be grounded in a dispositional world view.

In order to examine these substantive hypotheses it is, however, also necessary to determine whether self-definition is associated with the *type of problem* that a woman faces. That is, if we wish to conclude that interpretive differences between the two groups are meaningful, and that the differences are a function of the women's viewpoints, we must show that the differences are *not* a function of the actual problems faced by the two groups.

Method

Subjects and Procedure

The subjects in this study were 60 women, randomly selected from a larger longitudinal study of 122 women educated at an elite New England women's college. A six-picture TAT had been administered to the women under neutral conditions in the fall of their freshman year of college, as part of a larger study of college students. Ten years after their graduation from college (when they were 31 years old), they were mailed a questionnaire, inquiring about their activities in the years since college. In addition, all of the women were asked whether they would be willing to be interviewed. Because only 30% of the sample lived within a distance

permitting a personal interview, a random sample of 60 of the 122 women was selected to be interviewed over the phone. Of the 60 women, 57 were successfully contacted by telephone and interviewed for 20–30 minutes. The interviews were taped, with subjects' knowledge and permission, and were later transcribed for coding, with any identifying indications deleted. Complete, codable transcriptions were made for 51 of the 57 interviewees. The remaining 6 interviews were at least partially inaudible or unintelligible due to various mechanical failures.

Female interviewers³ conducted the interviewing according to the interview schedule outlined below, mainly attempting to ensure that in discussing the material, subjects covered all topics in the schedule. Subjects were surprisingly unruffled by the prospect of being interviewed over the telephone, and the resulting data appear quite open and complete. It is possible that the relative anonymity and impersonality of a telephone conversation encourages free and open conversation, since there is little opportunity for inadvertent expression of disapproval or disagreement. The hypothetical disadvantages of telephone interviews (lack of personal contact, lower rapport, etc.) did not seem to be significant factors in this study.

The Interview Schedule

Interviewers read the following paragraph to the subjects:

We are interested in studying stress in women's lives. We would like you to describe the period in your life that you think of as the most unhappy or upsetting time that you've lived through. Any period is all right, but choose a time when—for an extended period, not just briefly—things really seemed to go badly. The time needn't be catastrophic—just a time when things were not going well.

If subjects responded with a question about how long was "an extended period," interviewers were instructed to indicate that "the period should be about 6 months or more." If subjects indicated that nothing really terrible had happened, interviewers were instructed to respond, "just pick a time when you were less happy and more frustrated or distressed than usual." If subjects indicated that more than one period would qualify, interviewers asked them to select the period they felt was "most stressful for the longest period." In addition, interviewers used the following probes if the subjects' responses did not answer the questions involved: "What led up to this situation?" "What were the causes of this situation?" "Why did you find these particular things so upsetting?" "What did you do?" "Did you take any steps to deal with your situation?" "How did this all end?"

At the end of the interview, the interviewer concluded: We feel that women's lives are especially stressful, but we hope to understand these stresses better, so

³ The author is grateful to Betsy Harrington and Kathleen Finn for their assistance as interviewers.

we can help do something about them. Would you like a summary of our findings?

The interviewer then filled out a card with the subject's name and address, and feedback was later sent to the subject.

Coding the Data

I scored the original TATs, administered in 1960, blindly for self-definition before the interviews were conducted. I have demonstrated interrater reliability with other scorers on this variable ($\rho = .95$). In addition, I have demonstrated score-rescore and intercoder reliabilities (ρ s) above .94 on a subsample of the data scored for this study.

Briefly, the scoring categories in the self-definition scoring system⁴ can be summarized as follows:

Self-definition categories (scored +1). Causality: Use of explicit causal language. Reason-action sequence: The plot is organized in such a way that the final element of the story is an action or plan for action which follows logically from the preceding elements.

Social definition categories (scored -1). No causality: Events occur that appear to have no known causes or that are bizarre and unintelligible within the context of the story. Mental state ending: The plot is organized in such a way that the final element of the story is a character's feeling ("she was sad"), expressive behavior ("she cried"), or state of being ("then she was alone"). Ineffective actor: The final element of the story is phrased in passive voice or impersonal construction. It is explicitly stated that characters are helpless or that action is futile and pointless.

The scores for each picture (theoretical range = -3 to +2) are summed to create a single total score (theoretical range = -18 to +12). In this sample, the mean self-definition score was -.12 and the standard deviation was 3.40.

The interview transcripts were coded by a student assistant trained by me on pretest transcripts.⁵ This coder was blind to the identities and scores of the interviewees and was unaware of the nature and hypotheses of the study. The coder and I achieved intercoder reliability (category agreement) above .90 for all categories scored. The categories for coding the interviews can be summarized as follows:⁶

Overall ratings of the interview. The coder was instructed to perform an overall rating of the total interview for the following variables: (a) Clarity of formulation of the problem—Code the problem from 0 (quite unclear) to 2 (quite clear). (b) Clarity of explanation of causes of the problem—Again, rated clarity of the explanation of the causes of the problem on a 3 point scale from "unclear" to "clear." (c) Locus of the problem. Indicate whether the problem is described by the person as being located either within herself or outside herself. (d) Locus of the solution to the problem—Indicate whether the person sees the solution to the problem as located within her own control or outside her own control. (e) Content of problem—Indicate which of the following areas best describes the

Table 1
Self-Definition and the Content of the Problem

Content of problem	<i>n</i>	<i>M</i>	<i>SD</i>
Work or school ^a	14	.57	2.87
Relationships	15	-.13 ^b	2.67
Psychological	8	-.88	3.23
Death or illness	14	-.36	4.70

Note. $F = .51$, *ns*.

^a Including housework, and so forth.

^b Since some of the self-definition categories are scored -1, negative total or average scores are possible.

content of the problem described: (i) work or school (including work at home, if issue is *work*), (ii) interpersonal relationships, (iii) emotional and psychological problems (depression, alcoholism, etc.), or (iv) death and illness.

Type of response to problems. The coder was instructed to code the problem solutions as either: (a) No action—The subject indicated that she did nothing to solve the problem at all (e.g., "I did nothing," "I just waited," "Nothing could be done," etc.) or waited for the problem to be solved by some outside agent (e.g., "My husband got transferred so it got better."). (b) Noninstrumental action—The subject indicated that the solution to the problem was "distraction." That is, the subject's solution to the problem was to immerse herself in some *other* unrelated activity that helped her ignore the problem (e.g., "I was afraid of what would happen if I told him how I felt, so I joined a lot of clubs to keep myself busy," "I took up bridge"). (c) Instrumental action—The subject indicated that she solved the problem by initiating some action or set of actions (e.g., "I went back to school," "I told him how I felt," "I got a job," etc.) that was relevant to the problem at hand.

Results

First, as can be seen in Table 1, there were no differences in self-definition scores of women reporting problems in each of the content areas (work or school, other relationships, etc.). Any differences in the interpretations of self-defining and socially defined women's problems cannot reasonably be attributed to differences in the types of problems that they faced.

⁴ A detailed scoring manual, with illustrative examples and sets of practice stories with associated scoring, can be obtained by writing to the author.

⁵ The author is grateful to Gwen Arthur for this assistance.

⁶ Detailed instructions for coding can be obtained by writing to the author.

The first substantive hypotheses tested involved subjects' interpretation of their problems. As can be seen in Table 2, these hypotheses were supported. Because subjects whose problem involved death or illness might be less likely to hold alternative interpretations of their problem, these subjects were excluded from these analyses. However, results that included these subjects were substantially the same as those reported here. In both analyses, women who perceived their problem as located outside themselves and perceived the solution to their problem as located within themselves were significantly higher in self-definition. Similarly, women who cited more causes of their problem scored higher (though not significantly) in self-definition. Scores were also significantly correlated with the clarity of articulation of the problem ($r = .64$, $p < .001$) and clarity of explanation of the causes of the problem ($r = .73$, $p < .001$). Finally, women who presented their problems as involving a wider social context than the

Table 3

Self-Definition and Alternative Responses to Problems

Response	<i>n</i>	<i>M</i>	<i>SD</i>
Instrumental action	16	1.56*	3.71
Noninstrumental action	10	-2.10	3.14
No action	25	-.44	2.86

Note. $F(2, 48) = 4.25$, $p < .05$.

* This mean is significantly different from the means of those taking noninstrumental actions ($t = 2.59$, $p < .01$, one-tailed) and of those taking no action ($t = 1.89$, $p < .05$, one-tailed).

nuclear family were significantly more self-defining than women who did not.

The final hypothesis tested here was that self-definition would be associated with instrumental rather than noninstrumental or passive responses. As can be seen in Table 3, this hypothesis was also supported. Women who made instrumental responses were significantly higher in self-definition than women who made noninstrumental responses or no responses at all.

Table 2
Self-Definition and Interpretations of the Problem

Item	<i>n</i>	<i>M</i>	<i>t</i>
Locus of the problem*			
Within self	18	-1.67	4.10***

Narrow (only home)	19	-2.00	

Note. All p values are one-tailed.

* Problems classified as "death and illness" were excluded in these cases, since by definition they involved events both outside the self and outside the control of the self. Problems open to alternative interpretations (work, relationships, psychological) were included in the analysis.

* $p < .07$.

** $p < .005$.

*** $p \leq .001$.

Discussion

It is clear that self-defining and socially defined women do indeed interpret the problems that they face differently. As predicted, self-definition in women is associated with seeing one's problems as external but the solutions as within one's grasp (or internal). It is also related to seeing the causes of problems as multiple, and to explaining those causes clearly. Finally, self-definition is high among those who see their problems as part of a relatively wide social context, rather than in a narrowly domestic one. The world view expressed in these women's TAT stories is, then, reflected in the way they construe their own problems, 14 years later. Indeed, it can be said that the categories scored in the interviews are closely related to those scored in the TAT stories, and that therefore the relationships found here might better be interpreted as reliability estimates for self-definition rather than as genuine relationships between independent variables. Even if this argument is accepted, the consequent estimate of the stability of self-definition (.60-.70) over 14 years is itself remarkable enough. However,

the original measure was based on fantasy stories told about neutral pictures; the current interview coding was based on descriptions of actual problem situations and the methods used to handle those situations. Thus, on grounds of temporal separation, different base data, and different scoring systems, the two measures seem to be sufficiently different to justify the inference that self-definition (a dispositional world view) predisposes certain kinds of interpretations of problematic situations.

Finally, it seems reasonable to suspect that self-definition is also related to the actual problem-solving responses that the subjects reported having made. Though there is no independent evidence that these responses were actually made by the subjects, I have no reason to believe that the subjects distorted their responses, particularly since so few reported instrumental responses (31%), which are presumably the more socially desirable ones.

In summary, it is clear that self-definition and social definition are two implicit belief systems about the nature of external reality and one's own position within it with implications for an individual's interpretation of specific personal problem situations and for behavioral responses to those situations.

The implications of these findings should be clear. First, theoretically, the confirmation of a close link between individuals' general implicit belief system and their specific interpretations of and responses to particular problems indicates that coping responses, however "irrational," when viewed by an outside observer, may "make sense," given the world view of the subject. Moreover, this study indicates that it may be useful to examine both general stable belief systems (not only specific, situationally based attributions) and belief systems that are not necessarily conscious but are instead implicit in one's habits of thinking and organizing experience. Second, and more practically, if we wish to change ineffective coping strategies, we may find that it is sometimes useful to

intervene at the level of the global world view rather than at the particular response level. In addition, it is clear that as a construct, the predictive and theoretical utility of self-definition extends beyond the domain of career orientation and career activity. Finally, one implication of this study is that individuals' characteristic world views may often influence their particular judgments in stress situations. Further research examining the role of self-definition, and related dispositional variables, in determining alternative appraisals of threats in the laboratory (see, e.g., Lazarus, 1968) or alternative cognitive "sets" in problem-solving situations (see Scott & Howard, 1970) seems appropriate, given the strong association found in this study between self-definition and individuals' interpretations of their own personal problems.

Self Versus Ideal Self: A Comparison of Five Adjective Check List Indices

Harrison G. Gough

Institute of Personality Assessment and Research
University of California, Berkeley

Renato Lazzari and Mario Fioravanti

University of Rome

Five self versus ideal-self measures were defined on the 300-item Adjective Check List. Overall congruence was indexed by the phi coefficient for items and by the sum of the absolute differences on standard scores for the 24 scales (D-T). The absolute differences on the 24 scales were also correlated and factored in two samples: 100 American Air Force officers and 95 Italian young men applying for a national precollege military training school. Three factors common to both samples were identified. D-1, D-2, and D-3 measures of dissimilarity were obtained by summing the absolute differences on just those scales assignable to each of the three factors. Analyses of observers' ratings in the sample of American officers revealed phi, D-T, and D-1 to be indicative of superior personal and social adjustment and D-2 to suggest goal-oriented efficiency and diligence. D-3, in contrast, had rather unfavorable connotations. It is concluded that internal components of self-ideal congruence have differential implications that overall measures will obscure or even fail to detect.

A compelling aspect of the phenomenology of human experience is the sense of individuality, locus, wishes, fears, capacities, and continuity that behavioral scientists refer to as the *self*. By means of introspection and the observation of what others say and do, each person gradually evolves a notion of who he is and how he resembles and differs from other people. Various writers have attended to the way in which this self-concept or sense of identity may reflect social consensus (e.g., the "looking-glass self" of Cooley, 1902), the consequences of role-taking activity in childhood and later (Mead, 1934), and a growing awareness of the differences between what one wants and what the world is prepared to give (James, 1890).

The notion of an ideal self—what one would like or feels constrained to be—can also be posited. McDougall (1932), for example,

described a "self-regarding sentiment" and stressed the active process of comparison that goes on between the actual and the ideal self. Socialization, according to McDougall, is in part the resultant of a continuously more effective and encompassing reconciliation of these two selves. Allport (1961), in his concept of the *proprium*, sought to bring together seven facets of selfhood, including the bodily self, continuity, self-esteem, extension, imagination, rational coping, and goal-directed or propiety striving. The degree to which these facets of the self are harmoniously integrated will determine the degree to which an individual becomes what he or she is capable of becoming.

In this article we shall be dealing primarily with contrasts between the real and ideal selves, or aspects of the self, and with ways in which their congruence or discrepancies can be measured. There have, of course, been many attempts to assess these differences (Wylie, 1974), making use of methods such as the *Q* sort (Butler, 1968; Butler & Haigh, 1954), the semantic differential (Pervin &

Requests for reprints should be sent to Harrison G. Gough, Institute of Personality Assessment and Research, University of California, Berkeley, California 94720.

Lilly, 1967), the Interpersonal Check List (Leary, 1957), and the Minnesota Multiphasic Personality Inventory (Rosen, 1956). For the most part, these analyses have used a single score or index, based either on the responses to individual items under two conditions of administration, or on differences between scores on the scales of the instrument. The possibility that internal components or dimensions of similarity may be identified should also be considered. An overall index of congruence may mask or obscure important internal facets of similarity having different diagnostic implications.

Method

Subjects

Two samples were studied. The first consisted of 95 Italian males (M age = 15.5) who were applying for a national educational program sponsored by the Department of Defense. In educational background these applicants have the equivalent of 10 or 11 years of schooling in the American system. Successful applicants receive free education, food, and lodging, and incidental financial aid, much as do cadets or midshipmen in American military academies. A student in the Italian program may, on graduation, go on to one of the Italian military or naval academies, and the school, in fact, is viewed as a preparatory center for such training. The 95 applicants included in this study had come from all parts of the country to a testing center in Naples.

The other sample was composed of 100 male Air Force officers seen at the Institute of Personality Assessment and Research in Berkeley (MacKinnon, 1958). All held the rank of captain. Their mean age was 33.6, mean years of education 13.7, and mean years of service 11. Each officer spent 3 days at the Institute, participating in interviews, leaderless group discussions, testing sessions, laboratory exercises, and informal activity in which his behavior was observed and rated.

Tests

The principal testing device for this study was the Adjective Check List (ACL; Gough & Heilbrun, 1965). The ACL consists of 300 adjectives or adjectival phrases, from which the respondent selects those believed to be self-descriptive. The number of items checked is unspecified, as variation in endorsement is itself viewed as a personality variable. In addition to a score on number of items checked, there are 23 other scales, on all of which the standard scores are adjusted according to the number of items that are endorsed; this adjustment removes the influence of acquiescence from the 23 measures. Among the scales are those for self-confidence, self-control, achievement, dominance,

aggression, and deference. Testing time varies from 5 to 10 minutes. Italian norms for the ACL (Gough, 1968) were used for standardizing the scores of the 95 Italian males in this study.

The ACL was administered twice, once with normal instructions and the second time with a request to describe one's own ideal, defined as "the kind of person you would like to be—your personal ideal."

For the American sample, each officer was described on the ACL by 10 staff observers from the Institute. Tallies were made of the number of times each word had been checked, and these sums were used as descriptive scores. For example, if all 10 observers described an officer as "boastful," then his score on this item would be 10. If only 2 observers described him as "cooperative," then his score on this item would be 2. In this way 300 descriptive scores were obtained for each of the men.

Five ACL indices

To indicate the correspondence between self and ideal-self descriptions, five measures were used. The first of these was the phi coefficient for the adjectives checked and not checked in the two conditions. This coefficient reflects the degree of overall agreement between the descriptions of self and ideal self. The second index, called *D-T*, was also an indicator of overall agreement. It was defined as the sum of the absolute differences between the 24 standard scores on the ACL profiles for self and ideal self.

To develop indices of internal components, several methods were tried. One was to factor analyze the two 24×24 matrices of standard scores for the ideal self and then to compute difference scores separately for the scales included in each ideal-self factor. In each sample there were five ideal-self factors with eigenvalues greater than 1. Another approach was by way of the canonical correlations between the self and ideal-self scales in the two samples; the self-descriptive weights could then be used to compute estimates of the ideal vectors. These analyses identified two canonical variates in each sample. A third method was to factor analyze the 24 difference scores, based on the absolute discrepancies between the self and ideal-self scores for each of the scales in the checklist. Being based directly on the similarity of scores under the two conditions of testing, this third method appeared to be conceptually closest to the phenomenological notion of congruence between self and ideal self, and it was the one selected for subsequent analyses.

In the factor analyses for both Italian and American samples, there were four factors with eigenvalues equal to or greater than 1. After varimax rotation, these factors were compared for equivalence. The American factors 1, 2, and 3 were correlated .47, .58, and .68 with the Italian factors 2, 1, and 3. The fourth factors from each analysis, however, were ambiguously related and were therefore dropped from further consideration.

On the basis of these factor analyses, three difference scores were computed, each based on the absolute sum of the standard score discrepancies for the scales assigned to each factor. Specifically, *D-1* was based

on the scales from the American first factor and Italian second; it was defined as the sum of the absolute discrepancies on the scales for Number of Items Checked, Number of Favorable Items Checked, Personal Adjustment, Intracception, Nurturance, Affiliation, and Aggression. D-2 included the scales from the American second factor and Italian first; it was defined as the sum of the absolute discrepancies on the scales for Defensiveness, Self-confidence, Achievement, Dominance, and Endurance. D-3 was based on the two third factors, summing the absolute discrepancies on the scales for Libility, Exhibition, Autonomy, Change, Abasement, and Deference.

Results

Table 1 presents standard score means and sigmas for the self and ideal-self protocols of the American and Italian samples. As would

be expected, scores were generally higher under ideal-self instructions for scales measuring favorable or positive variables such as self-confidence and achievement and lower for scales measuring less desirable attributes such as the number of unfavorable words and abasement.

There were 12 differences that were in the same direction and that also yielded statistically significant ($p \leq .05$) *t* tests in both samples. If attention is paid only to the direction of difference, agreement was found in 22 of the 24 comparisons. A binomial test for this consistency gave a *z* value of 3.60, significant well beyond the .01 level of confidence. It can be concluded that there is appreciable correspondence in the two samples

Table 2

Means, Standard Deviations, and Intercorrelations of the Five Indices of Self Versus Ideal-Self Congruence in the American and Italian Samples

Index	Intercorrelation ^a					American ^b		Italian ^c	
	1	2	3	4	5	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
1. Phi	—	-.79	-.71	-.64	-.43	.50	.21	.42	.25
2. D-T	-.71	—	.82	.80	.65	190.45	87.47	183.80	77.97
3. D-1	-.68	.74	—	.50	.33	54.78	30.63	52.39	30.57
4. D-2	-.40	.78	.37	—	.33	41.16	28.05	42.48	24.29
5. D-3	-.51	.70	.28	.45	—	47.96	25.35	43.54	24.84

Note. D-T = the sum of the absolute differences between the 24 standard scores on the Adjective Check List profiles for self and ideal self; D-1 = the sum of the absolute differences on seven scales; D-2 = the sum of the absolute differences on five scales; and D-3 = the sum of the absolute differences on six scales. See text for specification of these scales.

^a Coefficients for the American sample are above the diagonal; coefficients for the Italian sample are below the diagonal.

^b *n* = 100.

^c *n* = 95.

in regard to the effect of the "ideal self" instructional set.

The five indices of agreement or disagreement between self and ideal-self description were next computed for the men in each sample. The means and standard deviations for each index are given in Table 2, along with the intercorrelations among the five measures of congruence.

The two overall indicators of similarity (phi and D-T) correlated $-.79$ in the American and $-.71$ in the Italian sample. These coefficients are in the expected direction, as phi reflects agreement and D-T reflects disagreement between the two conditions of testing. Although both coefficients are high, they are less than perfect and suggest that the relative degree of correspondence between the self and ideal-self descriptions of an individual will depend in part on the measure used to assess that correspondence.

The three remaining indices are each based on nonoverlapping subsets of scales from the ACL. For the American sample the median correlation among the D-1, D-2, and D-3 indices was .33, and for the Italian sample the median was .37. These coefficients are low enough to suggest that the three measures may be assessing different facets of the self versus ideal-self correlation.

The differences between the means of the American and Italian samples on the five

indices were all statistically insignificant, suggesting that these values may be taken as reliable benchmarks.

To examine the differences in diagnostic implications among the five measures, data were taken from the study of Air Force officers. As was mentioned earlier, each officer was described on the ACL by 10 staff observers. The number of times that each item was checked by these panels was taken as the descriptive score on the adjective; these 300 scores were then correlated with the five indices. To simplify the problem of interpreting findings, only the six adjectives with highest positive correlations and the six with largest negative correlations were selected for each of the five indices.

For the phi coefficient of similarity between self and ideal self, the six descriptions with highest positive correlations were cooperative (.28), adaptable (.26), planful (.26), outgoing (.25), efficient (.24), and thorough (.24). These coefficients are all significant beyond the .05 level of probability, and taken together they suggest a quite favorable picture of the individual whose self and ideal-self descriptions are similar. The six terms with largest negative correlations were slow ($-.25$), foolish ($-.24$), awkward ($-.22$), confused ($-.22$), unrealistic ($-.21$), and unfriendly ($-.18$).

For the D-T index of dissimilarity, we shall report first those adjectives having negative

correlations, as they are related to closer correspondence between self and ideal-self descriptions. The six with largest coefficients were thorough ($-.24$), planful ($-.20$), adaptable ($-.19$), cooperative ($-.19$), loyal ($-.18$), and reasonable ($-.18$). The cluster is distinctly favorable, but the degree of relationship is weaker than that for the phi coefficient. The six terms with largest positive values were headstrong (.26), opinionated (.25), boastful (.24), tactless (.24), arrogant (.23), and individualistic (.22).

For the D-1 index of dissimilarity, based on 7 of the 24 scales in the ACL, the six terms with largest negative correlations (and therefore associated with greater congruence of self and ideal-self descriptions) were thorough ($-.26$), cooperative ($-.25$), loyal ($-.25$), reasonable ($-.24$), considerate ($-.23$), and stable ($-.22$). The six terms with the largest positive correlations were boastful (.36), headstrong (.35), tactless (.33), opinionated (.32), arrogant (.31), and self-centered (.30).

Although there are differences in the particular words cited, the general tenor of the characterizations of officers showing greater self-ideal congruence on these three measures is favorable. Officers whose self-descriptions more closely approximate their ideal selves are viewed as more cooperative and less headstrong.

If the diagnostic implications of the three indices are more or less the same, which of the three measures can be recommended? One answer to this query can be based on the time needed for computation. For hand calculation, D-1 is easier to use than either D-T or phi, assuming that the two ACL protocols have been scored and profiled. Another answer can come from the certainty of the diagnostic implications. The median coefficient among the 12 given for each index can provide a crude measure of this certainty. For the phi index the median correlation was .245, for D-T it was .235, and for D-1 it was .280. The differences are slight, but they favor D-1.

Correspondence between self and ideal self has typically been interpreted as a measure of personal adjustment and stability. In the studies of psychotherapeutic outcome reported by Butler and Haigh (1954), an increase in the correlation between self and ideal-self *Q* sorts was accepted as a sign of improvement.

Wylie (1974), after reviewing a large number of studies, concluded that congruence between self and ideal-self description was generally taken as an indicator of self-acceptance and personal adjustment. The descriptive correlation found in our Air Force sample for phi, D-T, and D-1 gives some support to these inferences. A cautionary note should be sounded in regard to "oversatisfaction with self" (Block & Thomas, 1955). It is possible that too much congruence between self and ideal-self description could reflect insensitivity to personal problems, defensiveness, narcissism, and other undesirable attributes. A phi coefficient of .99 between self and ideal-self ACL protocols would not be viewed very favorably even by the most ardent advocate of the index. In our two samples, it should be remarked, exceedingly high phi coefficients were not encountered. For the Air Force sample, the highest coefficient was .85, and in the Italian sample the highest phi was .84.

In the Air Force sample, several ratings of personal soundness and social adjustment were available, contributed by the staff members who had interviewed and studied the officer. The rating for personal soundness correlated .13 with the phi index of correspondence between self and ideal self, $-.11$ with D-T, and $-.23$ with D-1. If an index of self versus ideal self is intended to carry a diagnostic implication of personal soundness or stability, it would appear from these three coefficients that the implication is strongest for the D-1 index. Another indication of adjustment came from a preliminary form of the Block *Q* sort (Block, 1961). An item in that form stated "Gets along in the world as it is; is socially appropriate in his behavior; keeps out of trouble." The mean staff placement of this item correlated .21 with phi, $-.14$ with D-T, and $-.26$ with D-1. Once again the advantage lies with the D-1 index. A final example can be taken from the Block item "is socially perceptive, responsive to interpersonal nuances." Correlations with mean staff placement of this item were .23 for phi, $-.20$ for D-T, and $-.28$ for D-1.

The second internal measure was D-2, based on the scales for Defensiveness, Self-confidence, Achievement, Dominance, and Endurance. When D-2 was correlated with the descrip-

tions, the six with the largest negative coefficients (i.e., checked more often about officers whose two protocols were more similar) were playful ($-.25$), efficient ($-.22$), adaptable ($-.21$), ambitious ($-.21$), sharp-witted ($-.21$), and thorough ($-.21$). The six descriptions with the largest positive correlations were slow (.28), shy (.26), awkward (.24), commonplace (.22), unaffected (.22), and slipshod (.21). Once again, officers whose two reports were more congruent were described more favorably, and those whose reports were less congruent were described less favorably.

In this regard D-2 resembles phi, D-T, and D-1. What, if any, are the differences? One difference is that D-2 carried no implications for the Q-sort item "gets along well in the world as it is," for which the coefficient was zero. For the rating of personal soundness, the coefficient for D-2 was $-.01$. Thus, although D-2 has implications for planfulness and efficiency, it does not have the implications that D-1 revealed for personal soundness and everyday social adjustment. On the Q-sort item "lacks confidence in own ability," the correlations for phi, D-T, D-1, and D-2 were $-.10$, $.02$, $-.10$, and $.19$, respectively. The sign of the coefficient for D-2 indicates that officers whose two descriptions were more discrepant were characterized by this lack. D-2, it appears, is reflective of a kind of problem-solving effectiveness but not of personal adjustment or soundness.

The third internal measure of congruence, D-3, may now be considered. The six adjectival descriptions correlating most strongly with similarity on D-3 were greedy ($-.20$), unselfish ($-.19$), fearful ($-.18$), self-punishing ($-.17$), ingenious ($-.16$), and changeable ($-.15$). The correlations for these six terms are low, and all save one are less than the coefficient of $.195$ necessary for significance at the $.05$ level of probability. It should be observed, nevertheless, that three of the six are clearly unfavorable in implication and that only two (unselfish and ingenious) are clearly favorable. D-3 therefore represents a distinct departure from the favorable implications of similarity between self and ideal found for phi, D-T, D-1, and D-2.

The six descriptions correlating most strongly with dissimilarity of the two protocols

on D-3 were daring (.25), tough (.24), hard-hearted (.23) attractive (.19), opinionated (.19), and strong (.19). Although these six relationships are of borderline statistical significance, they do cohere in a meaningful manner and suggest an individual possessing vivid and to some extent invasive social characteristics.

There were two ratings for which the correlations with D-3 were larger than for the other four indices. One of these was that for "ability to obtain sexual gratification," obtained from the psychiatric life history interview. The coefficients were $.05$ for phi, $.10$ for D-T, $.08$ for D-1, $.08$ for D-2, and $.18$ for D-3. The other was for the staff rating of apparent health and vitality, for which the coefficients were $.07$ for phi, $.12$ for D-T, $.09$ for D-1, $.07$ for D-2, and $.16$ for D-3. These are very low correlations, but they are of interest in that they show officers who are more discrepant on the D-3 index to possess more zest and vigor.

Discussion

One goal of our analysis was to determine whether or not internal components within the self versus ideal-self context might have implications different from each other and different from a global or overall index of congruence. We also wished to compare two methods of assessing overall congruence, one based on the scales of the ACL and the other taken directly from its items. A third aim was to enhance the generalizability and reliability of the measures by drawing on cross-cultural data in their derivation. In order to identify internal themes or components, factor analyses of difference scores for the 24 scales of the ACL on self and ideal-self protocols were conducted in American and Italian samples. Three of the four factors extracted in the two samples were compatible and were used to define three internal themes.

The two overall indices defined by the phi coefficient and a discrepancy score (D-T) based on all 24 scales were highly correlated with each other and gave rise to similar patterns of descriptive implications when correlated with adjectival descriptions and ratings in the American sample of 100 Air Force officers. The first internal component

(D-1) also correlated significantly with these two overall indices and produced a similar pattern of diagnostic implications. In general, the pattern for all three indices was indicative of positive personal adjustment, stability, and facility in coping with the world as it is. The level of these diagnostic implications was generally highest for the D-1 index. On the ACL, it follows, D-1 would be the best of the three measures of congruence between self and ideal self, if congruence is to be used as an indicator of personal adjustment and self-acceptance.

The other two internal indices differed somewhat from D-1 in their diagnostic implications. D-2 put more stress on personal efficiency, ambition, and work-related attributes and less on personal soundness and everyday social adjustment. D-3 revealed officers whose two protocols were more congruent to be more fearful, changeable, and self-punishing, whereas those whose protocols were more discrepant were more attractive, more daring, and more capable of seeking and attaining their goals in the sexual sphere.

Because of these differences in the diagnostic implications of the three internal indices, it is apparent that an overall index such as D-T must mask or conceal these variations. For example, the relatively unfavorable implications of congruence on the six scales included in the D-3 index are masked when a total discrepancy score based on all 24 scales is used. Differentiated measurement of similarity between self and ideal-self description is therefore to be preferred. The three ACL indices presented in this article may serve as examples of such an analytic perspective, even if future study finds other internal measures of congruence to be preferable. An obvious cautionary note, in this regard, is that the three components of congruence reported above were derived from samples of males only. Analyses of samples of females must be carried out to determine whether these or other indices of congruence will be most valid. Other ways of defining the ideal self could also be considered, for example, "the person my parents want me to be," "the person I would like to be in 10 years," and "myself, when I am at my best." The essential findings in our analysis, we conclude, are (a) that there are facets or aspects of

the congruence between self and ideal and (b) that these facets have different diagnostic implications. It follows that psychometric methods for assessing self-ideal congruence should include measurement of internal components as well as of overall or general correspondence.

Skill Training With Alcoholics

Edmund F. Chaney and Michael R. O'Leary
Veterans Administration Hospital, Seattle, and
Department of Psychiatry and Behavioral Sciences
University of Washington

G. Alan Marlatt
Department of Psychology, University of Washington

This study evaluated a short-term skill-training intervention that taught male alcoholics generation of appropriate behaviors in problematic situations. Forty alcoholics engaged in inpatient treatment were divided into three groups—a skill-training group, a discussion group, and a no-additional-treatment control group. A verbal role-playing measure of responses to situations associated with drinking behavior and relapse showed significant performance improvement of the training group as compared to the control groups. A 1-year posttreatment follow-up indicated that skill training decreased the duration and severity of relapse episodes. Behavior on the situational role-playing task predicted post-treatment adjustment. While pointing out limitations of skill training as implemented, results suggest its utility as one component of a multimodal behavioral approach to relapse in problem drinking and other problem areas such as drug addiction, smoking, obesity, and crime.

A social-learning approach to problem drinking (Bandura, 1969) suggests that in addition to the psychophysiological effects of alcohol, other factors such as cultural and subgroup mores, learning experiences within the family, peer modeling, instrumental functions, and expectancies are relevant to problem drinking. Thus, each individual's drinking behavior is likely to have multiple determinants and would require treatment incorpo-

rating a variety of techniques—a broad spectrum approach (Hamburg, 1975; Nathan, 1976).

One of the treatment strategies of broad spectrum approaches is to provide the problem drinker with the means of achieving reinforcement other than through the consumption of alcohol. This strategy involves identifying both the discriminative stimuli for drinking and the reinforcing consequences, and then making the occurrence of other more satisfying behaviors more likely through a variety of training techniques. Sobell and Sobell (1973), for instance, focused on the drinking behavior of their subjects. Subjects in the experimental group with a controlled-drinking goal were taught skills that theoretically would allow them to not drink or to drink in an appropriate social manner. Sobell and Sobell suggest that subjects who functioned well after discharge had learned to recognize discriminative stimuli for drinking and to generate alternative responses.

There is little systematic evaluation of training problem drinkers to generate alternative behaviors. Several investigators have

This research was supported by the Research Service, Seattle Veterans Administration Hospital, and by the University of Washington Alcohol and Drug Abuse Institute. This study is based on a dissertation by the first author submitted in partial fulfillment for the PhD degree at the University of Washington.

This study would not have been possible without the cooperation of William Hague, former Chief of the Seattle Veterans Administration Alcohol Treatment Program. Among the many students of behavior who took part in this study, the assistance of Ralph Boynton, Judith Chaney, Dennis Donovan, Dorothy Knapp, Flora Ostrow, Henne Queisser, and Demaris Rohsenow was particularly valuable.

outlined training approaches but have presented little evaluative data (Foy, Miller, Eisler, & O'Toole, 1976; Toomey, 1972). Skill-training techniques only recently have begun to receive systematic evaluation in other patient populations (Arnkoff & Stewart, 1975; Curran, 1977; Finch & Wallace, 1977; Goldsmith & McFall, 1975). Skill training is developing as a combination of methods of teaching the performance of new behaviors and of generating appropriate content of those behaviors. Instruction, modeling, coaching, and role playing, or behavioral rehearsal, appear to be additive components of training (Rich & Schroeder, 1976). Evidence also suggests that training tends to be situation specific (Eisler, Hersen, Miller, & Blanchard, 1975). Thus generalization of training is an important issue, and skill training should include systematic teaching of problem-solving skills so that subjects can analyze novel problematic situations and generate and evaluate adaptive responses (D'Zurilla & Goldfried, 1971).

Problem drinkers report that they use alcohol in a wide variety of stressful situations. Studies of drinking behavior in experimental situations help to confirm that heavy drinkers increase their consumption of alcohol when subjected to interpersonal stress (Allman, Taylor, & Nathan, 1972; Higgins & Marlatt, 1975; Miller, Hersen, Eisler, & Hilsman, 1974). To determine whether self-report and experimental findings are related to continued problem drinking, the characteristics of relapse situations need to be examined. Unfortunately, few investigators have reported situational characteristics of relapses as they happen following treatment.

The present study follows Marlatt's (1978) categorization of relapse situations of male alcoholics following aversion-conditioning therapy. It was found that relapse situations could be assigned reliably to the following types: (a) frustration and inability to express anger (29%); (b) inability to resist social pressure to drink (23%); (c) intrapersonal negative emotional state (10%); (d) inability to resist intrapersonal temptation to drink (21%); and (e) other, or no response (17%). Training situations used in the present study were balanced among the first four categories.

The present study addressed two questions: Does skill training increase problem drinkers' effectiveness in responding to stressful situations? and Does an improvement in psychosocial problem solving have an effect on the subsequent occurrence of problem drinking behavior? The population of problem drinkers considered in this experiment consisted of volunteers in intensive inpatient alcoholism treatment. Subjects were assigned randomly to one of three groups: experimental skill training, discussion control, or no-additional-treatment control. The experimental group used modeling, role-playing, and coaching techniques to work through the problem-solving steps of problem definition and formulation, generation of alternatives, and decision making. Optimal alternatives were rehearsed. The discussion control group talked about the same situations that the experimental group practiced solving, but they did not use role playing, modeling, or coaching. A second control group received no additional training beyond the regular treatment regimen. Training effects were assessed on a verbal role-playing measure of responses to situations associated with drinking behavior and relapse (the Situational Competency Test; SCT). Subjects also were given a structured follow-up interview at 1-month, 3-month, 6-month, and 12-month intervals following discharge. Specific hypotheses tested were: (a) The experimental treatment group would show a pre-post increase in competency in handling problematic situations as measured by the SCT, compared with the competency level of the two control groups, which would not change; and (b) the experimental group would show superior posthospitalization adjustment as compared with the control groups.

Method

Subjects and Treatment Setting

Patients in the Seattle Veteran's Administration Alcoholic Treatment Program (ATP) formed the potential subject pool. All male patients residing in the program 19-26 days and agreeing to stay for the full program were asked to volunteer. Participation was voluntary, and refusal to take part did not jeopardize treatment. All subjects had a primary diagnosis of alcoholism, and none were actively psychotic or organically impaired to the extent of requiring extended

domiciliary care in the opinion of the treatment staff. All subjects continued to participate in the regular treatment program.

Patients admitted to the ATP initially entered an orientation phase in which detoxification was completed and acute medical problems were resolved. After a minimum of 5 days, the patient progressed to the evaluation phase, a 2-week period during which the patient attended six 60-minute small group therapy sessions, videotaped replays of the group sessions, daily therapeutic community groups, and several education-oriented lectures and movies. The program was abstinence oriented, and group therapy, the primary therapeutic modality, examined ongoing relationships and feelings in the patient community with the assumption that understanding and working out relationships with other group members would carry over to important outside relationships, obviating the need for alcohol.

At the end of the 2-week evaluation period, the ATP required patients to make a commitment for an additional 2 weeks of inpatient treatment, a 4-week day program, and 1 year of a weekly aftercare group. Patients who could not make this commitment were referred elsewhere. Treatment activities continued through the day program as described for the evaluation period. Single men were required to live in a supervised halfway house during the day program and for an additional 2 months thereafter. Married men returned home but participated in a weekly couples group for 3 months.

Of the 70 persons asked to participate, 56 consented. Of this group, 6 dropped out of the research before being assigned to a group. An additional 10 patients dropped out during the training phase: 4 were skill-training subjects, 3 were discussion subjects, and 3 were controls. This left 40 subjects who were retested and followed: 15 in the experimental group, 13 discussion controls, and 12 no-additional-treatment controls. Within the limitation of their sequential entry into the program, subjects were assigned to the three groups on a random basis.

Subjects included 2 black men and 1 Native American. Subjects' mean age was 45.6 ($SD = 9.32$). Seventeen men were married; 3 were single; 20 were separated or divorced. The mean number of years of education was 12.3 ($SD = 2.46$). Average total monthly income prior to hospitalization was \$335 ($SD = \470). Mean months employed in current job was 18.6 ($SD = 50.1$). Modal social class was IV (i.e., lower middle) computed from the Hollingshead *Two-Factor Social Position Index* (Hollingshead, Note 1). Seven subjects were court referred; the remainder voluntarily presented themselves for treatment. The average number of years of self-acknowledged problem drinking for the sample was 17.0 ($SD = 10.18$). Subjects reported an average of 3,250 drinks ($SD = 2,450$) consumed during the 6 months prior to admission. Drinks were defined as 1 ounce (29.57 cm³) of 86-proof liquor or its equivalent in alcohol content. Subjects drank an average of 122 days ($SD = 67.1$) during the 6-month period. Eleven subjects reported binge-drinking patterns; 25, steady drinking; and 4, a mixed pattern. The average

number of previous treatment attempts was 1.3 ($SD = 1.27$). Average number of months elapsed since first alcohol treatment attempt was 61 ($SD = 76.1$).

With the exception of the reported number of problems due to drinking, $F(2, 37) = 8.8$, $p < .001$, there were no significant differences among the three subject groups on pretreatment demographic and drinking history measures. The drinking problems measure consisted of a checklist with eight items such as job loss, marital difficulties, and illness. The skill-training group reported more problems prior to treatment than the discussion group ($M = 6.5$, $SD = .9$ vs. $M = 4.4$, $SD = 1.5$, $p < .05$, using Duncan's new multiple-range test). The control group's mean of 5.4 ($SD = 1.5$) was not different from the other groups.

Development of Skill Assessment and Training Procedures

Several sources were used to generate situations likely to be problematic for the present population of excessive drinkers. These included (a) descriptions of relapse situations by Marlatt (1978) gathered in individual interviews with his patients during follow-up; (b) suggestions by treatment personnel of two treatment facilities (Seattle Veteran's Administration Hospital and Mendota State Hospital, Wisconsin) who work with male alcoholics; (c) interviews with alcoholics on the Seattle ATP; and (d) modifications of situations from several inventories designed to assess assertive behavior (Eisler, Miller, & Hersen, 1973; Lawrence, 1970; McFall & Marston, 1970). Eighty situations were assembled and worded to be specific enough to elicit a small number of appropriate courses of action but general enough to be useful as standardized situations for this population. This 80-item inventory (the Situational Difficulty Questionnaire¹) was presented to 40 patients on the ATP who did not take part in any other phase of the study. They were instructed to rank each situation with regard to the difficulty that it would present if encountered in the natural environment. Situations were divided into four categories: (a) frustration and anger; (b) interpersonal temptation; (c) negative emotional state; and (d) intrapersonal temptation. The eight situations judged most difficult within each of the categories were retained for use in the study.

In frustration and anger situations, the person experiences the blocking of a goal-directed activity and/or hostility toward some person or external event. For example:

Before you entered the alcoholism treatment program, your employer, who knew about your drinking problem, said that you could have your job back when you got out of the hospital. When you leave

¹ Copies of the Situational Difficulty Questionnaire, Situational Competency Test, training manual, and follow-up questionnaires for subject and collateral reports are available from the first author.

the program, you find that the company has hired someone to take your place.

In interpersonal temptation situations, the person experiences explicit or implicit pressure by other people to drink. For example:

You are eating at a good restaurant on a special occasion with some friends. The waitress comes over and says, "Drink before dinner?" Everyone else orders one. All eyes seem to be on you.

In negative emotional state situations, the person experiences feelings such as loneliness, depression, boredom, futility, malaise, or nervousness in the absence of clear-cut environmental or interpersonal stimuli. For example:

You get up Saturday morning and realize that you don't have anything planned to do during the day. You sit around for a while, but you begin to feel bored and restless.

In intrapersonal temptation situations, the person experiences a desire or compulsion to drink in the absence of specifically identified external or internal factors. For example:

You have been out of the hospital a couple of months now and haven't taken a single drink. However, you've been wondering how well the treatment really worked, and you get to feeling like taking a drink to test it out.

Assignment of situations into the four categories was assessed independently by two judges (a clinical psychologist and a clinical psychology graduate student) with 94% agreement. Of the 32 situations, 16 were used for training purposes, leaving 16 available for pretreatment and posttreatment testing. No two training and assessment situations were exactly alike.

Pretreatment Measures

Testing situations were assembled into the SCT (see Footnote 1). Situation descriptions were tape recorded, ending with the phrase "What would you do or say?" The subject was instructed to imagine that the situation was actually occurring and to say the words or describe the action that he would use to respond to the situation. Subjects' responses were tape recorded. For the pretest a sample situation was provided to check the subject's understanding of the task. A first version of the SCT was administered to 10 subjects who did not participate in other phases of the research to check that the situation descriptions were clear and that they elicited varied responses.

Four scoring measures, latency, duration, compliance, and specification of new behavior, were chosen. Latency of response was defined as the elapsed time from the termination of the recorded situation to the semantic beginning of the subject's response, excluding disfluencies and hedging. Response duration was the number of words in the response, excluding side comments to the experimenter. Compliance was a dichotomous score indicating whether or not the

subject gave in to the situation without attempting to exert control that would change or influence the course of the situation. Drinking, giving in to a demand, not expressing feelings, and tacitly agreeing to criticism were scored as compliant. Specification of new behavior was also a dichotomous score indicating whether the description of the problem-solving behavior to be performed was given in sufficient detail so that someone else could use the description as a guide to perform the behavior. In other words, a response must have specified one alternative rather than a class of alternatives: "I would come up to the ward" versus "I would get help." This measure was applicable to both interpersonal and intrapersonal situations.

Subjects took the SCT prior to treatment, immediately after, and 3 months following discharge from the hospital. Measures were summed across situations for each subject. All scoring for the four measures across the three administrations was done at the same time by the same rater (a clinical psychology graduate student) who was blind to subject identity and test order. Reliability of the compliance and specification measures was assessed by Pearson correlations of the primary rating of 20 randomly selected protocols of 16 situations, with ratings by an independent rater (also a clinical psychology graduate student; compliance $r = .85$, specification of behavior $r = .82$).

During the evaluation phase of the ATP, the patient received psychological testing including the Shipley Institute of Living Scale (Shipley, 1940), a test of cognitive ability and intellectual impairment. Impairment, expressed by the Conceptual Quotient (CQ), indicates the extent to which the individual's abstract thinking falls short of his or her vocabulary.

After agreeing to participate in the study, all subjects were interviewed using a shortened version of the Drinking Profile (Marlatt, 1976). This structured interview instrument systematically assesses psychosocial functioning and drinking behavior prior to treatment. The Drinking Profile was administered by one of three graduate psychology students. Each had previous clinical experience and was trained by giving at least four supervised administrations of the Drinking Profile. These three experimenters also gave the SCT and conducted most of the follow-up interviews. During the period of the study, they had no involvement in the subjects' treatment, routine or experimental.

Training of Therapists

A training manual (see Footnote 1) was written for the skill-training and discussion treatment procedures. The manual provided an orientation for the therapists, specified introductory statements for the two types of groups, and gave procedural guidelines. It also gave suggestions for working with each of the four situational categories, and for skill training it summarized the problem that each situation presented and gave instructions for evaluating the situational responses. Six therapists were trained to conduct the two groups. The two primary therapists were females: a vocational rehabilitation technician who was experienced in conducting behavioral group therapy and a

clinical psychology graduate student who had completed her internship. Two male clinical psychology graduate students engaged in their internship served as cotherapists during the first half of the study. When they finished their internship, they were replaced by two male recovering alcoholic counselors. The counselors had prior experience leading groups and were both working toward degrees in social work. Therapist training consisted of reading the training manual and background material and role playing the therapy procedures for three 1-hour sessions.

Therapists worked in male-female pairs, and each therapist was involved in an equal number of skill-training and discussion groups. All of the skill-training and discussion sessions were observed by one of the investigators. The observer and therapists met after each group for feedback to minimize drift in technique over time.

Treatment Procedures

Training for the experimental and discussion groups consisted of eight semiweekly 90-minute sessions. Cohorts of 3-5 subjects met with two therapists. Starting dates of skill-training and discussion groups alternated so that if any changes took place in the ATP while the study was underway, the skill-training and discussion groups would be affected equally. As dictated by random assignment, control subjects were distributed individually throughout the duration of the study.

Skill-training group. Skill-training procedures were based primarily on a series of experiments by McFall (McFall & Lillesand, 1971; McFall & Marston, 1970; McFall & Twentyman, 1973), who investigated effective components of assertion training. The content of training was based on D'Zurilla and Goldfried's (1971) stepwise analysis of problem solving. The steps are (a) orientation, (b) definition, (c) generation of alternatives, (d) decision making, and (e) verification.

After giving a general orientation to problem-solving procedures, therapists read a description of a problematic situation. Subjects discussed how they viewed the situation and generated possible ways of responding to it. The therapists pointed out when group members defined the situation differently and what the consequences of different definitions were for problem solving. The probable consequences of the different alternatives proposed by members were discussed, and, if necessary, the therapists proposed alternatives. For interpersonal situations, one therapist chose an alternative, explained the basis of this choice in terms of probable consequences, and then modeled a response, with the cotherapist playing the other person in the situation. For intrapersonal situations one of the therapists engaged in a monologue, explicitly defining the problem, generating alternative solutions, deciding which one would maximize long- and short-term gains and could be performed, and outlining steps to implement the solution. After this initial phase, each group member decided on a particular response and rehearsed it, receiving feedback from the group on the probable consequences of his response. If the therapists and group felt that the response was not likely to solve the

problem that the situation presented, the subject was required to repeat his performance. After each subject had rehearsed, a member summarized the method for generating and evaluating an adequate response to that situation. Two prepared situations were introduced during each session, covering four situations in each of the four categories during training. Subjects also rehearsed one or two situations of their own devising that they felt might be problematic after discharge from the hospital.

In summary, skill-training groups incorporated instruction, modeling, behavioral rehearsal, and coaching, both of actual response behavior and of the cognitive process for generating the response. Subjects were taught how to define the problem that a situation presented by specifying the elements and to generate alternatives and think about the long- and short-term consequences. Finally, the behavior rehearsal phase of training provided practice in carrying out adaptive responses and served as a role-playing form of verification, assessing the adequacy of the problem-solving process.

Discussion group. Discussion group procedures were based on the rationale that problem drinkers do possess the necessary skills to analyze and cope with high-risk situations, but, because of feelings of anger, anxiety, dependency, or depression, they do not effectively use those skills. Discussion procedures focused on eliciting the feelings that may be present in problematic situations and examining subjects' reactions and motivations relevant to similar situations of the past with the logic that self-understanding and more effective coping behavior should result. Thus, in the discussion groups, after giving the orientation, the therapists introduced the same problematic situations as were used in the skill-training group. Then, in a nondirective manner, they encouraged expression and discussion of feelings relevant to the situations.

Control group. A third group of subjects received all assessment measures at the same intervals as other subjects but participated only in regular ATP treatment activities.

Posttreatment Assessment and Follow-Up

Immediately following the eight sessions of treatment, subjects were retested on the SCT. Subjects typically were discharged from the day treatment phase of the program and began weekly aftercare groups the week following completion of the experimental treatment program.

Follow-up procedures were dated from the time the subject left the day treatment phase of the ATP. At 1-month, 3-month, 6-month, and 12-month intervals, subjects were interviewed using a standardized follow-up questionnaire (see Footnote 1), which was designed to provide information compatible with the Drinking Profile. The form assesses occupational stability, living situation, and use of therapeutic supports and provides drinking disposition data by asking about periods and rates of drinking and periods of hospitalization or incarceration. The questionnaire also permits a detailed examination of relapse situation characteristics by

recording place, people present, activity, environmental events, inner thoughts and feelings, and reasons for starting to drink. Subjects had initially consented to have their self-reports verified, and this was done at each follow-up interval through contact with at least one relative, friend, employer, or treatment agency.

At the 3-month interval, the SCT was readministered in person or by telephone in the few cases in which the subject had moved out of the area. In the latter cases, the self-report interview instrument also was administered by telephone. Subjects who had dropped out of treatment and/or moved out of the area often were difficult to locate. Court records, Veteran's Administration files, employers, relatives, friends, and other patients provided leads. In a few cases it was necessary to wait out a period of heavy, sustained drinking before the subject could be interviewed. Throughout follow-up, the subjects' confidentiality was protected.

Results

Situational Competency Test

Heterogeneity. The four variables on which the SCT was scored were intercorrelated for the preadministration, exit, and 3-month postadministration to determine to what extent the derived measures were independent of each other. SCT analyses, which included exit and 3-month posttest data, were based on an n of 37, because 1 discussion group subject's exit data were lost through instrument failure and 2 skill-training subjects' 3-month posttest

data could not be gathered at the required interval. One of the latter subjects was on a binge, which later resulted in his death due to medical complications. The other subject had moved and later was located out of the area.

Table 1 shows that the four SCT measures were independent, with two notable exceptions. At all three test administrations, noncompliance was related positively to specification of new behavior. At exit, duration of response was positively related to specification of new behavior, indicating that longer responses were likely to specify concrete behavior for most subjects only at the end of the inpatient phase of the treatment program.

Treatment effects on the SCT. There were no significant pretreatment group differences on the four dependent measures derived from the SCT. Treatment effects were analyzed by using the prescores to compute residuals of the exit and 3-month posttest scores, which then were subjected to a repeated measures analysis of variance (Huck & McLean, 1975). As Table 2 shows, for duration of response, the group main effect was significant. Planned comparisons indicate that at immediate retest, the skill-training group had a significantly longer duration of response than the discussion group, $t(34) = 1.69$, $p < .05$, and the control group, $t(34) = 2.44$, $p < .01$. As Figure 1

Figure 1. Response duration measured by the Situational Competency Test pre, post, and 3 months after training. (X = skill training; Y = discussion; Z = no treatment control.)

shows, by the 3-month posttest, these differences had diminished.

Specification of new behavior also showed a training effect, with the group main effect significant. Planned comparisons show that the skill-training group performed better on exit testing than both the discussion group, $t(34) = 2.44$, $p < .01$, and the control group, $t(34) = 1.69$, $p < .05$. By the 3-month posttest (see Figure 2), the skill-training group was still significantly different from the discussion group only, $t(34) = 1.69$, $p < .05$. No significant differences due to training were found on the latency or noncompliance measures.

Drinking Behavior and Social Adjustment

Posttreatment drinking behavior. Drinking behavior was assessed primarily by drinking disposition measures (Sobell & Sobell, 1973).

Days during the follow-up period were categorized as (a) voluntary abstinence; (b) forced abstinence (i.e., jailed or hospitalized); (c) controlled drinking, defined as any days during which 6 or fewer drinks were consumed or any isolated 1- or 2-day sequence when between 7 and 9 drinks were consumed; and (d) drunk days, defined as isolated days during which 10 or more drinks were consumed or as any day that was part of a period of more than 2 days during which 7-9 drinks were consumed. Total amount drunk and average drinking period length for those subjects who drank were computed for the year. Results exclude the skill-training subject who died.

Of the drinking disposition measures, too few subjects (nine in all) reported controlled drinking days for this category to be a useful outcome indicator. Preliminary analysis of the other drinking-related measures indicated that

Figure 2. Specification of behavior measured by the Situational Competency Test pre, post, and 3 months after training. (X = skill training; Y = discussion; Z = no treatment control.)

within-cell variances were heterogeneous. The Bartlett-Box F (Winer, 1971) was significant for all measures except days voluntarily abstinent. Therefore, statistical analyses were performed on logarithmically transformed scores (Winer, 1971, p. 400).

First, the two control groups were compared on the drinking disposition measures using t tests. No significant differences were found, just as no differences between the two groups had been observed on the SCT. Thus these groups were pooled for comparison with the skill-training group. Since multiple dependent variables were involved, a multivariate analogue of the t test, Hotelling's T^2 (Winer, 1971), was applied to the following group of measures: days abstinent, days hospitalized, drunk days, total amount drunk, and average drinking period length; $T^2(5, 33) = 2.73$, $p < .05$. Having found the vectors of group means to be significantly different, individual t tests were

used to determine which measures accounted for the difference.

The skill-training and control groups were found to be significantly different on three of the five measures: days drunk, $t(37) = -2.21$, $p < .05$; total number of drinks, $t(37) = -2.01$, $p < .05$, and average drinking period length, $t(37) = -2.32$, $p < .05$. Table 3 gives untransformed means and standard deviations for these and the other outcome measures for the 1-year follow-up period. As the table shows, for the follow-up year, the skill-training group had an average number of days drunk one-sixth that of the pooled control group, drank one-fourth as much, and had an average drinking period length less than one-eighth as long.

To determine whether the improvement in drinking behavior generalized to areas of functioning that had not been specifically targeted by the intervention, two other self-

Table 3

Posttreatment Adjustment: 12-Month Outcome

	2	24.2	17.8		

^a Group 1 (*n* = 14) received skill training; Group 2 (*n* = 25) subjects were in the discussion or non-additional-treatment groups. One Group 1 subject died after 5 months of an alcohol-aggravated illness following a 2-month period of substained drinking.

^b Five subjects were retired or pensioned (2 in Group 1 and 3 in Group 2).

* *p* < .05.

report measures of outcome were examined: job performance (retired and fully pensioned subjects excepted) and continued engagement in the ATP outpatient treatment for which the subject had contracted. These measures did not show significant group differences, suggesting that the effects of the intervention are relatively specific to drinking behavior.

Relapse Situation Category Analysis

A relapse was defined as the initiation of a drinking period lasting 1 or more drunk days. Successive relapses for the same individual were considered to be distinct when the subject reported different setting events for drinking periods, which were separated by at least 2 abstinent or controlled drinking days. For the year, 25 subjects (10 in the skill-training group, 6 discussion, and 9 control) reported a total of 55 relapses (*M* = 2.2, *SD* = 1.29, range = 1-6). Number of relapses for the subject groups did not differ significantly.

Relapse situations were categorized independently by two clinical psychology graduate students into the four categories used throughout the study, with 81% agreement. Disagreements were resolved by consensus. The largest

number of relapses were of the negative emotional state type (43%). The interpersonal temptation category was represented by 17% of the relapses, whereas frustration and anger situations and intrapersonal temptation each comprised 15.5%. Of the relapses, 9% were not classifiable either because of lack of sufficient information or failure to fit any of the four category descriptions.

Prediction of Outcome

To evaluate the ability of the SCT to predict posttreatment drinking behavior and social adjustment, a multiple regression approach incorporating drinking history and demographic measures was used. Due to the small number of subjects, the number of potential predictors was first reduced by correlating pretreatment variables with the 1-year outcome indices. Controlled drinking days were excluded since so few were reported. The three measures most highly related to each outcome index were entered into a stepwise regression analysis along with the three SCT exit measures: latency, duration, and specification of behavior. Noncompliance was not included because of its high collinearity with the specification measure.

Table 4
Prediction of 1-Year Outcome Variables

Outcome variable	Predictor	<i>r</i>	<i>F</i>	<i>R</i>	<i>R</i> ²	Overall <i>F</i>

Table 4 summarizes the significant findings giving simple and multiple correlation coefficients and *F* values for individual and combined predictors. For all outcome indices, the predictive ability of the SCT latency measure was comparable or superior to that of the most highly related demographic and drinking history measures. For instance, for days abstinent, latency of response to problematic situations accounted for 53% of the variance. For days employed and average drinking period length for which pretreatment measures entered the regression equations first, the latency measure still contributed significantly. This analysis establishes a relationship between ability to respond to problematic drinking-related situations on a verbal role-playing instrument and actual drinking-related behavioral functioning following treatment.

Discussion

The skill-training method successfully evaluated here views the client as an active organism

who can learn to cope with future problems. Approaches that *only* use verbal persuasion or substitute medication or supportive social groups for the treated addiction do not assist the client in reevaluating expectations of personal efficacy. Recent reviews (Bandura, 1977) have suggested that a person's expectations of success or failure in coping with situations are important determinants of behavior. Efficacy expectations are modifiable through corrective experience and training.

This study indicates that problem drinkers' responses to situations that present a high risk of relapse can be improved through training. Since the focus was on training problem-solving techniques, rather than a repertoire of specific responses, the testing situations were not the same as the situations used in training. The skill-training intervention produced longer and more specifically appropriate verbal behavior in response to these novel problem situations. These effects would not have been found unless generalization took place.

The measure of noncompliance demonstrated a ceiling effect. Both before and after treatment, subjects usually indicated that they would exercise control over problematic situations. The noncompliance of problem drinkers' verbal behavior in situations potentially leading to drinking probably reflects social desirability and demand characteristics of the assessment procedures rather than behavior *in vivo*. The sensitivity of the SCT to demand characteristics might have been accentuated by using the instructional set "what would you do" rather than "what are you going to do." On the other hand, pretesting indicated that such instructions were necessary to minimize frequent denial: "That will never happen to me!"

The apparent decline of training effects on the 3-month posttest may reflect in part that alcoholics typically appear for treatment after a prolonged period of heavy drinking. Consequently, they demonstrate cognitive impairment as evidenced by their low average Shipley CQ. The overall mean of 82 ($SD = 15.8$) is in the "moderately suspicious" range (Shipley, 1940). Research on the same population using Halstead-Reitan measures of cognitive functioning confirms this finding (Schau & O'Leary, 1977). The permanence of alcoholics' cognitive impairment and its relation to their drinking behavior is unknown (Rankin, 1975). Therapies incorporating concept learning (such as skill training) when used with recently sober problem drinkers whose cerebral functioning is at least temporarily impaired may require booster sessions administered on an outpatient basis for maximum enduring effect. The continuing beneficial impact on drinking outcome that was found may be due to the environmental support from significant others occasioned by successful coping with problematic situations encountered early in the follow-up period.

Evaluation of the finding that skill training had a beneficial effect over and above that of the regular treatment program on post-hospitalization adjustment is dependent on the validity of the self-report outcome measures. This study corroborated self-report with data systematically collected from collaterals. Comparison of subject and collateral reports suggests that certain measures of

drinking behavior are more reliable and less likely to elicit socially desirable answers than others. For instance, if a person goes on a binge and blacks out, the amount drunk during the binge will not be remembered accurately. In this respect, drinking disposition is an improvement over other measures.

Follow-up data indicated that during the posttreatment year the drinking behavior of the skill-training group and the control groups significantly diverged as measured by (a) days drunk, (b) amount drunk, and (c) length of drinking periods. Differences were found even though the regular treatment program was intensive. In the most successful behavioral study to date (Sobell & Sobell, 1973), much of the differential improvement in the functioning of experimental subjects as opposed to controls seemed to be accounted for by different amounts of controlled drinking (Lloyd & Salzberg, 1975). The fact that very few controlled drinking days were reported in the present study may be related to the treatment goal of abstinence. The skill-training sessions were conducted in accordance with the abstinence-oriented philosophy of the treatment program. The focus was on how not to drink rather than how to moderate drinking. However, these and other results (Armor, Polich, & Stambul, 1976) suggest that a majority of problem drinkers will resume drinking to some extent following treatment, no matter what that treatment consists of. It seems sensible not to encourage drinking but to stress prevention by preparing patients to cope with drinking situations when they inevitably arise.

A finding that supports the clinical utility of the SCT and the social competence approach to problem drinking is that the men in this sample who had shorter response latencies to role-played problematic drinking problem situations drank less, were employed more, and had more regular aftercare attendance following treatment. Of all variables, this indicator of problem-solving skill was most highly related to outcome. Avoiding problem drinking completely may be even more dependent on the ability to quickly generate an alternate response to drinking than on the precise content of the response, as modified by the skill-training procedure used here.

(Schwartz & Gottman, 1976, make a similar point regarding college students' responses to problematic situations.) Although latency is a difficult response characteristic to modify (Eisler, Hersen, & Miller, 1973; Hersen, Eisler, & Miller, 1974), future skill training might do well to incorporate explicit procedures to test whether this relationship is of a causal nature.

In conclusion we wish to stress three points.

(a) Skill training (even including booster sessions) *alone*, although a potentially effective component of multimodal treatment, probably would not be sufficient treatment for a rather socioeconomically and cognitively impaired population such as that studied here. (b) The treatment strategy evaluated here included not only the training of problem-solving skills but also behavioral rehearsal of specific responses (the verification phase). Determining which of the techniques used was most responsible for change requires further investigation. Future studies might draw on Bandura's (1977) self-efficacy conceptualization of behavior change when assessing individual elements of skill training and incorporating additional treatment components. (c) Further research on the characteristics and prevention of relapse in a variety of problem areas such as drug addiction, smoking, obesity, and crime is necessary and warranted. This study, in combination with Marlatt and Gordon's recent results (in press), suggests that different client populations find different types of relapse situations most problematic. A reliable taxonomy of relapse situations related to the characteristics of different client populations, together with further refinement of skill-training procedures, would help in the attempt to match the treatment to the person.

Evaluating Alcoholism Treatment Programs: An Integrated Approach

Ruth C. Cronkite and Rudolf H. Moos

Department of Psychiatry and Behavioral Sciences
Social Ecology Laboratory, Stanford University School of Medicine
and Palo Alto Veterans Administration Hospital, Palo Alto, California

This article examines the interrelationships among five major sets of variables (social background, intake symptoms, program type, treatment experiences, and perceptions of the environment) that are related to posttreatment functioning of alcoholic patients (alcohol consumption, rating of drinking problem, physical impairment, and occupational functioning). The sample consisted of 429 patients selected from five different treatment programs. The relative importance of each set of variables as predictors of outcome was estimated by constructing block variables, using path analyses, and partitioning the explained variance. The results showed that (a) the combined explanatory power of the program-related variables is considerably more than would be expected from previous research; (b) the importance of patient background relative to intake symptoms varies with the outcome criterion being used; (c) both the treatment experiences and the patient's perceptions of the treatment environment are strong predictors of outcome; and (d) a substantial proportion of the explained variance is shared between patient-related and program-related variables, suggesting important patient-program selection and congruence effects.

One of the major issues in longitudinal studies of alcoholic patients is assessing the relative importance of patient background and treatment programs in determining outcome. Although contradictory findings have been reported, previous research has generally suggested that patient characteristics at intake are most strongly related to outcome and that treatment programs have little effect once sociodemographic and functioning characteristics at intake are taken into account (Armor, Polich, & Stambul, 1976;

Craft, Sheehan, Driggers, & DuBois, 1975; Gerard & Saenger, 1966; Pokorny, Miller, & Cleveland, 1968; Ruggels, Armor, Polich, Mothershead, & Stephen, 1975).

A related issue involves the relative contributions of different types of patient characteristics—in particular, the extent to which outcome is related to social background on the one hand and drinking symptoms at intake on the other. No clear-cut pattern of findings has been reported on the relative importance of social background variables (such as socioeconomic or marital status) compared to intake symptoms (such as alcohol consumption or behavioral or psychological impairment at intake) in predicting outcome (Armor et al., 1976; Craft et al., 1975; Ruggels et al., 1975).

Inferences pertaining to both of these issues have been primarily based on examination of the increments in explained variance (Armor et al., 1976; Bromet, Moos, Bliss, & Wuthmann, 1977; Craft et al., 1975; Ruggels et al., 1975). This method is asymmetric

The research was supported in part by National Institute for Alcohol Abuse and Alcoholism Grant AA02863 and by Veterans Administration Research Funds. The article is based on a presentation to the Evaluation Research Session, Western Social Science Association meetings, Denver, Colorado, April 1977. Ruth Cronkite is also affiliated with Mills College, Oakland, California.

in that it attributes variance shared by two or more sets of variables to the set that is entered first in the regression analysis (such as patient background variables), and thus may overestimate the contribution of the first set by crediting it with both its unique and shared variance. In contrast, the increment in explained variance attributed to the set of variables added last (such as program-related variables) represents only the explained variance that is unique to that set of variables, not the variance that is shared with variables that have been entered earlier. Consequently, previous inferences about the relative effects of program-related variables, social background characteristics, and intake symptoms on outcome may be misleading.¹ Such inferences have important policy implications for alcoholism treatment. For example, if the unique variance attributed to program-related variables is small, and the variance that is shared with patient background variables is attributed only to background characteristics, then researchers may conclude that treatment effects are negligible and thus recommend less expensive and more uniform treatment programs.

Another unresolved question raised by longitudinal studies of alcoholics is the role of different types of program-related variables in predicting outcome. The relationship of treatment variations to outcome has been approached in several ways. Armor et al. (1976) and Kissin, Platz, and Su (1970) focused on the type and amount of treatment both within and across programs. Bromet et al. (1977) examined the effect of level of participation on outcome in several different treatment programs. In addition to studying the effects of a variety of treatment experiences and treatment programs, Bromet, Moos, and Bliss (1976) have focused on another dimension of program-related variables, a patient's perceptions of the treatment environment. This approach is based on research which suggests that the social environments of psychiatric and correctional programs may be important factors in influencing outcome (Ellsworth, Maroney, Klett, Gordon, & Gunn, 1971; Moos, 1974b). Each of these aspects of treatment variations has been studied separately, but their effects relative

to each other have not been examined within a single study.

The purpose of this article is to develop an integrated approach to studying alcoholism treatment programs that will facilitate clarification of the following issues: (a) What are the interrelationships among patient social background variables, intake symptoms, treatment programs, treatment experiences, perceptions of the treatment environment, and outcome? (b) What is the relative importance of program-related variables compared to patient background characteristics in predicting outcome? (c) What is the relative importance of a patient's social background compared to intake symptoms in predicting outcome? (d) What are the roles of different aspects of treatment variations in predicting outcome?

A Model of Treatment Outcome

In most longitudinal studies of alcoholic patients, the dependent variables are one or more outcome criteria related to posttreatment functioning, such as rehospitalization, alcohol consumption, and occupational, physical, and psychosocial functioning. The independent variables vary across studies, depending on their focus. From reviewing previous research, the independent variables can be divided into "blocks," labeled *Blocks 1, 2, 3, 4, and 5*. Block 1 consists of a set of sociodemographic variables known to be related to drinking patterns, such as age, sex, ethnicity, marital status, and socioeconomic status. Block 2 includes a patient's drinking symptoms at intake, more specifically, the type and severity of alcoholism-related characteristics, such as alcohol consumption, drinking patterns, physical impairment, and behavioral impairment. Blocks 3, 4, and 5 refer to program-related variables. Block 3 includes the type of program; Block 4 includes the amount of various treatment experiences, such as therapy sessions, Alcoholics Anonymous (AA) meetings, antabuse, and

¹ See Newton and Spurrell (1967a, 1967b) and Mood (1971) for a complete technical discussion of partitioning the sum of squares in regression analysis and Coleman (1975) for a discussion of this issue when applied to school effects.

so forth, in which the patient participates; and Block 5 includes the patient's perceptions of the program environment.

As mentioned earlier, researchers have focused on comparing Blocks 1 and 2 with Blocks 3 and 4 (and to a lesser extent Block 5) in an attempt to assess the effect on outcome of program-related variables compared to patient characteristics at intake (Armor et al., 1976; Bromet et al., 1977; Ruggels et al., 1975). Some of these investigators have also compared Block 1 variables with Block 2 variables to focus on the relative contributions of social background and intake symptoms (Armor et al., 1976; Ruggels et al., 1975) in explaining outcome.

The use of block variables not only serves to group conceptually similar variables, but it also allows one to formulate a model that summarizes the hypothesized causal interrelationships among the block variables, as shown in Figure 1. Blocks 1 and 2 represent characteristics of a patient at the time of entering a program. Although some of the Block 1 variables can be regarded as antecedents of the onset of alcoholism (Armor et al., 1976), they also reflect a patient's social characteristics at the time of intake to treatment and can thus be specified as correlated with intake symptoms (represented by the bidirectional line, r_{12}). Not only are both social background (Block 1) and intake symptoms (Block 2) related to a patient's outcome after treatment, as shown by the paths p_{61} and p_{62} , but they are also important determinants of the type of program that a patient enters (e.g., patients who enter private treatment programs tend to be older, married, and to have higher income, educational, and occupational levels; see Bromet et al., 1977), as specified by p_{32} and p_{31} .

The treatment experiences that a patient receives are almost entirely determined by the program that a patient enters, which is specified by the path p_{43} . Bromet et al. (1976) have shown that patient characteristics such as social background and intake symptoms are unrelated to the treatment experiences received by patients. Consequently, the paths from Blocks 1 and 2 to Block 4 are not in-

cluded in the model (i.e., p_{41} and p_{42} were constrained to be zero).²

Similarly, since the environments of treatment programs vary considerably in the degree of support, autonomy, clarity, staff control, and so on, the program is expected to be an important determinant of a patient's perceptions of the treatment environment, represented by p_{53} (Bromet et al., 1976). In addition, it is possible that patients' perceptions of the treatment program may be affected by their characteristics at intake, as specified by the path p_{51} . All of the program-related variables, Blocks 3, 4, and 5, are expected to directly affect outcome, as indicated by Paths p_{63} , p_{64} , and p_{65} .

This model summarizes the hypothesized causal interrelationships among the sets of variables related to outcome. It also displays the causal reasoning behind the practice of entering blocks of variables sequentially into the regression analyses in which social background (Block 1) and intake symptoms (Block 2) precede the type of treatment program, and, in turn, the treatment program (Block 3) precedes the other program-related variables, treatment experiences (Block 4), and perceptions of the environment (Block 5). Furthermore, this model allows one to establish both the direct and indirect paths through which each block of variables can affect and be affected by other blocks of variables. For example, social background not only has a direct effect on outcome that is independent of the other variables in the model, via p_{61} , but it can also indirectly affect outcome via intervening variables, such as the program ($p_{63}p_{31}$). That is, the compound path $p_{63}p_{31}$ represents the indirect effect of social background that is mediated by the program (or the effect of social background that is shared with the program effects). Other indirect paths include the compound paths in the model that link two variables via one or more intervening variables (e.g., $p_{65}p_{51}$, $p_{65}p_{53}p_{31}$, and $p_{64}p_{43}$). When all of the direct

² Analyses that were undertaken with a fully recursive model revealed that the omitted paths in Figure 1 (p_{41} , p_{42} , p_{52} , and p_{54}) were all close to zero, thus providing empirical support for the more constrained model.

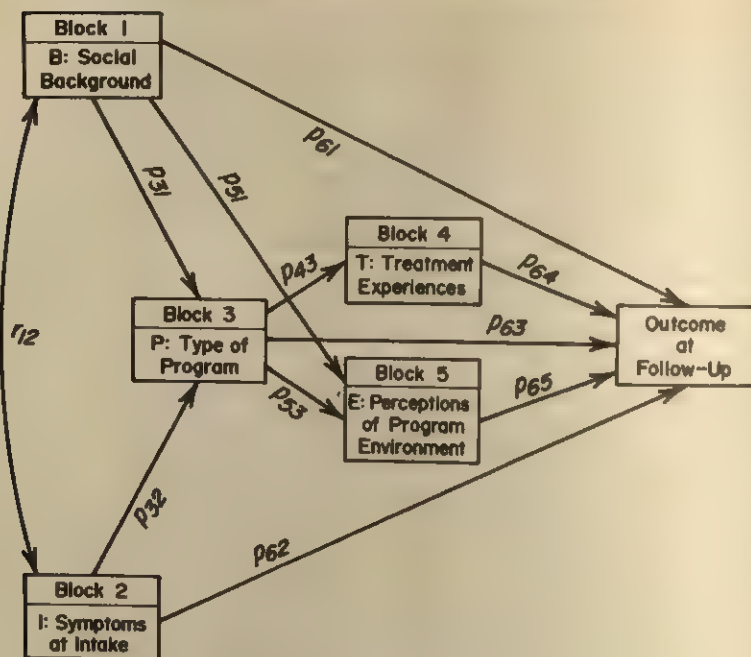

Figure 1. A model of treatment outcome.

and indirect effects are taken together with information on the unique and joint explained variance, it is possible to assess more accurately the extent to which each set of block variables contributes to explaining treatment outcome.

Method

Sample, Programs, and Data

The sample consisted of 429 patients from five residential alcoholism programs. These facilities, which were selected because they are representative of the major types of treatment settings for alcoholics, include (a) a Salvation Army program offering milieu therapy and vocational rehabilitation to skid-row alcoholics; (b) a public hospital-based facility offering milieu and group treatment and anti-anxiety medicines and sedatives to low-income patients; (c) a county-funded halfway house operating as a therapeutic community with individual and group therapy and recreational activities; (d) a private aversion-conditioning medication-oriented program treating middle-class and upper-middle-class patients; and (e) a private milieu-oriented program emphasizing group and family therapy (as well as medication) for middle-class and upper-middle-class patients. (For more detailed information, see Bromet et al., 1976.)

Patients in the study included approximately 80%

of all admissions during a 10-month average period. Most of the nonparticipants were those who dropped out of the program within a few days. Unlike many other studies, the sample is representative of patients from a wide range of socioeconomic characteristics such as education, age, income, employment status, and marital status.

The data consisted of (a) a background information form administered to patients shortly after admission to a program; (b) a treatment experiences form completed by a staff member after a patient left the program; (c) the Community-Oriented Programs Environment Scale (COPES) administered to patients about 2 weeks after admission to measure their perceptions of the program environment; and (d) a follow-up information form completed by the patient approximately 6 months after discharge.³

Background information form. The following data on a patient's social background and drinking symptoms at intake came from the background information form:

1. Social background (five items): age, sex, marital status (married, not married), ethnic group (white, nonwhite), and highest grade of school completed.
2. Drinking symptoms at intake: (a) alcohol consumption, the quantity of alcohol in ounces of ethanol from beer, wine, and hard liquor consumed on a typical drinking day (Armor et al., 1976); (b) physi-

³ Although the validity of data based on self-report of alcoholics is controversial, Sobell and Sobell (1975) have shown that it may be relatively reliable and valid.

cal impairment, a subscale derived from the mean of 10 items rated on 5-point scales (from never to often), referring to how often patients experience delirium tremens or shakes, memory lapses or black-outs, dry heaves or cold sweat, upset stomach, dizzy spells, and so forth; (c) subjective rating of drinking problem, ranging from 1 for no problem to 5 for quite often a problem; and (d) occupational functioning, which refers to whether the patient had been unemployed during the last 6 months prior to admission (yes/no).

Treatment experiences. Together the programs offered a wide range of treatment experiences. Two programs (the hospital-based program and the private milieu-oriented program) offered ataractic medication, psychotherapy, and educational interventions. Two others (the Salvation Army program and the public hospital-based program) emphasized primarily psychotherapeutic and educational interventions, whereas the aversion-conditioning program relied almost entirely on its conditioning schedule (using emetic and ataractic drugs) and minimized other types of treatment experiences. All programs offered AA sessions, even though they varied in the extent to which they were emphasized. A total of 12 types of treatment experiences were offered across the five programs: antianxiety medications, sedatives, vitamins, antabuse, psychotherapy sessions, house meetings, AA sessions, educational lectures and films, recreational activities, other informal group activities, and (at the Salvation Army program only) Sunday worship and spot jobs. The amount of treatment, level of participation, and length of stay varied considerably among the patients within each program.

Perceptions of the environment. The COPEs was used to measure a patient's perceptions of the program environment. The COPEs is a scale designed to measure 10 dimensions of the treatment environment by having patients respond to 100 true-false items, which fall into 10 subscales. Three of the subscales measure personal relationship dimensions (Involvement, Support, and Spontaneity). Four subscales assess personal development or treatment program dimensions, such as the extent to which patients are encouraged to be self-sufficient and independent (Autonomy), to prepare for the future (Practical Orientation), and to have insight into their problems (Personal Problem Orientation and Anger and Aggression). The last three subscales (Order and Organization, Program Clarity, and Staff Control) assess system maintenance dimensions (see Moos, 1974a, 1974b).

Follow-up information form. The follow-up evaluation, conducted approximately 6-8 months after discharge, was obtained using a questionnaire identical in content to the background information form administered at intake. The follow-up form was completed by 429 patients (87% of the 494 patients available for follow-up). Four outcome criteria were selected to assess major dimensions of posttreatment functioning: alcohol consumption in ounces of ethanol, subjective rating of drinking problem, physical

impairment, and occupational functioning. These four dimensions correspond to the four intake symptoms drawn from the background information form.

Procedure

There were three major steps in carrying out the analyses: (a) construction of "block" variables; (b) the use of path analysis to compute the direct, indirect, and total effects among the block variables in the model; and (c) the partitioning of the sum of squares of the regression analysis into the unique variance attributed to each block variable and the joint variance shared by combinations of block variables.

Construction of block variables. Coleman (1975) has suggested a procedure for constructing a single composite or block variable from a set of variables that are similar conceptually (e.g., variables such as age, sex, marital status, education, and ethnicity can jointly define a composite variable called "social background"). A composite variable is computed as a weighted sum of the variables that compose a block. The weights are the regression coefficients obtained when the set of variables are the only independent variables used to predict the dependent variable. For example, a single variable representing social background would be the weighted sum of the various social background variables, the weights being the regression coefficients obtained when a particular outcome criterion (such as alcohol consumption) is the dependent variable. Such a composite variable no longer has a natural metric, but it still ranges from low to high levels of social background, where a high level refers to those combinations of social background characteristics that are associated with better outcome.

Four composite variables representing social background (Block 1), program type (Block 3), treatment experiences (Block 4), and perceptions of the program environment (Block 5) were constructed separately for each of the four outcome criteria. That is, by using a particular outcome criterion, such as alcohol consumption, regression coefficients were obtained separately for each set of variables that composed a block variable and were used as weights to construct that block variable. Four sets of four block variables were computed from regression coefficients obtained for each of the four outcome criteria.⁴

Instead of constructing a composite intake symptom variable, the intake symptom corresponding to

⁴To compare the regression results using the newly constructed block variables with a full regression model, the coefficients of the block variables were multiplied by each of the coefficients actually obtained from a full regression model. This comparison confirmed that the general pattern of results is similar even though the composite variable model is more restricted (in the way that it allows the variables within and across models to be cross-correlated).

the outcome criterion in each model was selected. Using a single intake symptom in this case serves to clarify the relationship between the same type of alcoholism-related characteristics at two points in time.⁵

Calculation of direct, indirect, and total effects. By using path analysis with recursive models, it is possible to calculate the direct, indirect, and total effects of each block variable (and the single intake symptom) on the other variables in the model. The general method involves estimating the structural equations that correspond to a recursive model, such as the one presented in Figure 1. Alwin and Hauser (1975) suggested a general method for decomposing total effects into their direct and indirect effects through the estimation of successive reduced-form equations.

The model illustrated in Figure 1 can be represented by the following set of equations:

$$X_3 = p_{31}X_1 + p_{32}X_2 + e, \quad (1)$$

$$X_4 = p_{43}X_3 + u, \quad (2)$$

$$X_5 = p_{51}X_1 + p_{53}X_3 + v, \quad (3)$$

$$X_6 = p_{61}X_1 + p_{62}X_2 + p_{63}X_3 + p_{64}X_4 + p_{65}X_5 + w, \quad (4)$$

where X_1 = the block variable representing social background, X_2 = the selected intake symptom, X_3 = the block variable representing "program type," X_4 = the block variable representing "treatment experiences," X_5 = the block variable representing "perceptions of the program environment," X_6 = the selected outcome criterion, and e , u , v , and w are random error terms.

Consistent with conventional notation in path analysis, direct effects are represented by p s (e.g., p_{31} is the direct effect of social background on outcome). Total effects are represented by q s (e.g., q_{31} is the total effect of social background on outcome). A total effect is the sum of the direct effect (e.g., p_{31}) and any indirect effects via intervening variables (e.g., $q_{31} = p_{31} + p_{32}p_{43} + p_{32}p_{43}p_{51} + p_{32}p_{43}p_{51}p_{61} + p_{32}p_{43}p_{51}p_{62}$). The total effect is equal to the direct effect if there are no indirect effects (e.g., $q_{31} = p_{31}$), and it is equal to an indirect effect if there is no direct path (e.g., $q_{41} = p_{43}p_{31}$).

All of the direct, indirect, and total effects corresponding to the model presented in Figure 1 and specified by Equations 1-4 were estimated for the four outcome criteria. This decomposition of the total effects allows for a detailed examination of the interrelationships among the variables related to outcome.

Path coefficients (standardized regression coefficients), rather than unstandardized regression coefficients, were used because the block variables do not have a natural metric. Unstandardized coefficients are difficult to interpret when it is unclear what is meant by a unit increase in a block variable. This problem is avoided with path coefficients, since they represent changes in standard deviation units.

Partitioning the sums of squares. As noted above, previous research on alcoholism treatment programs,

which compares the amount of explained variance accounted for by different types of variables, has been asymmetric because of the sequential order in which variables are entered into the regression analysis. That is, the variance associated with the variable entered first includes not only the explained variance that is unique to that variable but also the variance that it shares with other variables that are entered later in the analysis. Consequently, the increment in explained variance reflects only the unique variance associated with the added variable, since any variance that it shares with preceding variables has already been accounted for.

Newton and Spurrell (1967a, 1967b) and Mood (1971) have outlined a procedure for making more symmetric comparisons by calculating the unique and shared variance accounted for by each variable or combination of variables in a regression equation. This analysis was carried out for each of the four outcome criteria by varying the sequential order in which the four block variables and the single intake variable were included in the regression. The explained variance was then partitioned into the variance attributed uniquely to each block variable (or the single intake variable) and the variance shared by the various combinations of variables.⁶

Results

Three sets of analyses are presented: (a) the interrelationships among the patient background and program-related variables; (b) a comparison of total, direct, and indirect effects of patient background and program-related variables on outcome; and (c) an examination of the unique and shared explained variance attributed to the variables used to predict outcome.

The path diagrams of the four selected outcome criteria are shown in Figures 2-5. The path coefficients corresponding to the effect of the patient background variables (social background and the intake symptom) on the program-related variables (program type, treatment experiences, and perceptions of the treat-

⁵ Some analyses were conducted using composite intake symptom variables. The results were very similar to those that used only a single intake symptom, with a tendency for the composite variable to have a slightly stronger effect on outcome.

⁶ Since any analysis may be subject to particular biases and instabilities, both path analysis and partitioning of the explained variance are used. This allows one to have more confidence in the results and minimizes the likelihood that the results are due to possible instabilities or biases in the regression weights.

ment environment) are listed in Table 1, along with estimates of their total and indirect effects. The rest of the path coefficients shown in Figures 2-5, as well as the corresponding total and indirect effects, are displayed in Table 2. These estimates reflect the effect of the patient background variables (social background and intake symptom) and the program-related variables (program type, treatment experiences, and perceptions of the treatment environment) on outcome.

Relationship of Patient Characteristics to Program-Related Variables

Determinants of program selection. The estimates of p_{81} shown in Figures 2-5 (also listed in Table 1) for the four outcome criteria show that the composite background variable is an important determinant of the type of program that a patient enters. (All are statistically significant at the .05 level.) The path coefficients across three of the models are very close, ranging from .463 in the physical concomitants model to .559 in the alcohol consumption model. The slightly lower coefficient in the occupational functioning model may result from the nature of this particular outcome criterion [i.e., the effect of the intake characteristic, occupational functioning (p_{32}) probably has accounted for some of the effect of social background, because of its similarity to the other social background characteristics].

The estimates of the effects of the other intake functioning characteristics (p_{32}) indicate that these three alcoholism-related symptoms are not consistently strong determinants of the type of program that a patient enters, as shown by coefficients ranging from $-.150$ to $.015$. The two intake variables that had relatively strong effects (occupational functioning and physical concomitants) are those that were most highly correlated with social background.

Determinants of treatment experiences. The only variable hypothesized to have a direct effect on treatment experiences is the program type, and, in fact, the estimates of the effect of the program (p_{43}) are relatively large (and statistically significant), ranging from .460 to .689 across all four models (see Table

1 and Figures 2-5). This finding is consistent with expectations, since the programs almost entirely determine the type of treatment experiences that a patient has.

Although neither social background nor the intake symptom were hypothesized to have a direct effect on treatment experiences, their indirect effects via the program type were estimated and are listed in Table 1. The indirect effects of the intake symptoms via the program type ($p_{43}p_{32}$) are relatively small, as shown by estimates ranging from $-.089$ to $.007$. In contrast, social background seems to have a stronger indirect effect, with estimates of $p_{43}p_{31}$ of .124 and .360. This implies that patients with a "higher" level of social background tend to enter and/or more actively participate in programs offering those treatment experiences that are associated with better outcome.

Determinants of perceptions of the environment. The estimates of p_{51} in Table 1 show that social background has a positive effect on a patient's perceptions of the program environment (with the exception of the model of occupational functioning), suggesting that patients with higher levels of social background characteristics tend to perceive the environment slightly more positively. The decomposition of the total effect of social background on perceptions of the environment (q_{51}) indicates that most of the total effect is due to the indirect positive effect of social background via the program type ($p_{53}p_{31}$), implying that those patients with higher levels of social background characteristics enter programs that provide more positive treatment environments. Similar to the effects of the program type on treatment experiences, the direct effects of the program type on perceptions of the environment (p_{53}) are relatively close and large (ranging from .434 to .552), indicating that the major determinant of a patient's perceptions is the program that the patient is in.

Relationship of Patient Background and Program-Related Variables to Outcome

Table 2 displays the direct, indirect, and total effects of each of the five variables hypothesized to affect outcome. The results show

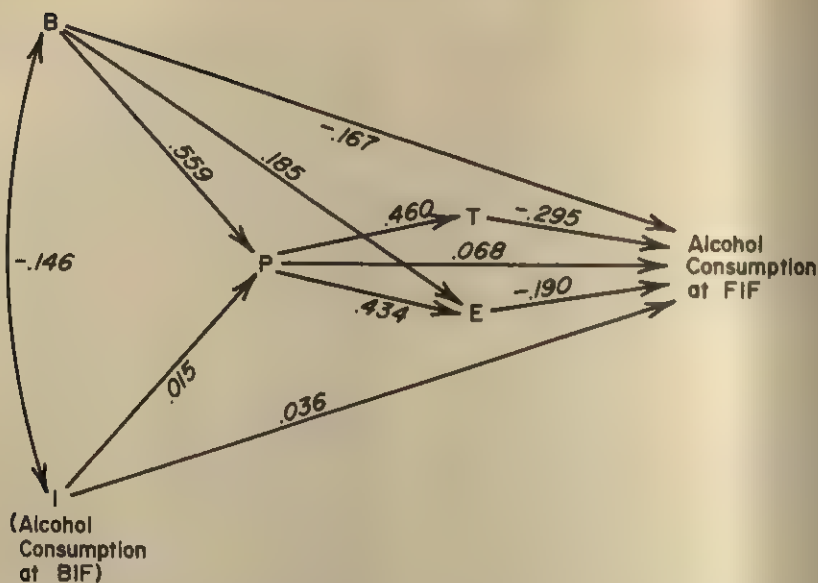

Figure 2. Estimation of path coefficients for alcohol consumption. (FIF = follow-up information form; BIF = background information form; B = background; I = intake; P = program; T = treatment experiences; E = treatment environment.)

some clear-cut consistencies across the models. The estimates of p_{61} (three of which are statistically significant) suggest that the higher the level of social background, the less severe the alcoholism-related symptoms are at fol-

low-up. Similarly, there is a relatively strong association between a patient's intake symptoms and the corresponding outcome criterion at follow-up, indicated by the estimates of p_{62} (except for a weak effect in the alcohol

Figure 3. Estimation of path coefficients for rating of drinking problem. (FIF = follow-up information form; BIF = background information form; B = background; I = intake; P = program; T = treatment experiences; E = treatment environment.)

Figure 4. Estimation of path coefficients for physical concomitants. (FIF = follow-up information form; BIF = background information form; B = background; I = intake; P = program; T = treatment experiences; E = treatment environment.)

consumption model). In fact, for three of the outcome criteria, the intake symptoms had slightly stronger direct effects than social background. The indirect effects of social background that are mediated by the program-related variables together represent between 11% and 73% of their total effect,

whereas the indirect effects of the intake symptom together represent between 7% and 23% of their total effect. These results indicate that in three of the models, a substantial proportion of the total effect of social background is via indirect effects that are shared with the program-related variables. In con-

Figure 5. Estimation of path coefficients for occupational functioning. (FIF = follow-up information form; BIF = background information form; B = background; I = intake; P = program; T = treatment experiences; E = treatment environment.)

trast, most of the total effect of the intake symptoms is direct (77%–93%) and thus not shared with the program-related variables.

There is a strong total effect of program type on outcome (q_{63}). When the treatment experiences and perceptions of the environment are taken into account, however, the program variable has little direct effect (p_{63}) (i.e., almost all of the total effect of the program is mediated by the two program-related

variables, shown by the indirect effects, $p_{64}p_{43}$, and $p_{65}p_{53}$, in Table 2).

Treatment experiences (p_{64}) and perceptions of the environment (p_{65}) are both strongly associated with outcome. For all of the outcome criteria except occupational functioning, the direct effect of the perceptions of the environment (p_{65}) is surprisingly strong, suggesting that perceptions of the treatment program may be important predic-

Table 1

Direct, Indirect, and Total Effects of Patient-Related Block Variables on Program-Related Block Variables

Dependent	Variable	Type of intake and outcome criterion used			
		Alcohol consumption	Rating of drinking problem	Physical concomitants	Occupational functioning

* Within the context of the causal model used here (see Figure 1), the total effects of treatment experiences and perceptions of the environment, q_{64} and q_{65} , respectively, are the same as their direct effects, p_{64} and p_{65} . Consequently, they are only listed under the direct effects. The total effects listed here were calculated as the sum of the direct and indirect effects.

* $p < .05$ (calculated for direct effects only).

tors of outcome. However, there is substantial interdependence among the program-related variables; only 0%–27% of the direct effect of treatment experiences and 1%–33% of the direct effect of perceptions of the environment are independent of all prior variables (social background, intake symptoms, and program type).⁷

Unique and Joint Contributions of the Explained Variance

Table 3 presents the results of partitioning the explained variance for the four outcome criteria. The first five rows display the unique and shared variance attributed to the patient background variables, and the next six rows show the unique and shared vari-

ance attributed to the program-related variables. The rest of the table displays the explained variance that is shared among combinations of the patient-related and program-related variables.

The pattern of results is similar to those obtained from the path analysis. In general, both social background and the intake symptoms contribute substantially to the explained variance, with the combined contribution of their unique and shared variance ranging from 12% to 61% of the explained variance. In three of the models, the unique contributions

⁷ These percentages were calculated by subtracting out all other paths that are causally prior to the direct path of interest. (See Coleman, 1975, for a more detailed discussion of these procedures.)

of the intake symptoms are stronger than the unique explained variance attributed to social background. When taken together with the path analyses, the findings suggest that the intake symptom has a relatively stronger relationship to outcome than does social background.

The total of the unique and shared variance attributed to the program-related variables ranges from 16% to 57% of the explained variance. The unique variance accounted for by the program type is very small, whereas that accounted for by the treatment experiences and perceptions of the environment is larger. This implies that most of the unique variance accounted for by the program-related variables is due to either treatment experiences or perceptions of the environment. For two outcome criteria (rating of drinking problem and physical concomitants), percep-

tions of the environment account for more explained variance, whereas treatment experiences have more explanatory power for the other two (occupational functioning and alcohol consumption). Consistent with the results of the path analyses, the unique contribution of perceptions of the environment is almost as strong or stronger than any of the patient background variables (in three models) or any of the other variables in the model (in two models).

Since each program determines its treatment experiences and the environment it creates, some of the explained variance is shared among combinations of the program-related variables. This corresponds to the path analysis, which shows that most of the total effect of the program type is due to its indirect effects that are shared with the other two program-related variables.

In comparing the contribution of the program-related variables with that of the patient background variables, there is no group of block variables that clearly has the most explanatory power across all models. Patient-related variables account for more explained variance than program-related variables when predicting occupational functioning, whereas their relative contributions are approximately equal when predicting physical concomitants. In contrast, the explained variance attributed to program-related variables is greater in the models of rating of drinking problem and alcohol consumption.

Discussion

We have used an integrated approach to examine the interrelationships among five major sets of variables that are related to treatment outcome. This was done by (a) formulating a model that explicitly specified the hypothesized causal ordering among these sets of variables; (b) constructing block variables to summarize the effects of sets of conceptually similar variables; (c) decomposing the total effects of each block variable into its direct and indirect effects; and (d) partitioning the explained variance into the unique contributions of each block variable and the shared contributions among combinations of block variables. The findings clarify some important issues concerning the way in which patient-related and program-related variables contribute to explaining outcome.

Consistent with previous research (Armor et al., 1976; Bromet et al., 1977; Craft et al., 1975; Ruggels et al., 1975), the results show that social background and intake symptoms are relatively strong predictors of outcome. In addition, although most of the total effect of the intake symptoms is direct, social background has substantial indirect effects that are mediated by the program-related variables. These effects represent shared variance between sociodemographic characteristics and program-related variables and cannot be attributed solely to either set of variables alone.

Although the relative importance of social background and intake symptoms is not consistent across all four models, the intake symptoms have stronger direct effects and

account for a larger proportion of the explained variance for three of the four outcome criteria. Even though no clear-cut pattern has been reported in previous research, these findings suggest that the intake symptoms may be slightly stronger predictors of some outcome criteria than social background. More research on different types of patient functioning characteristics is needed to clarify this issue.

Previous research has reported that treatment does contribute to improved functioning from intake to follow-up; that is, recovery rates of treated alcoholic patients vary directly with the amount of treatment, length of stay, and level of participation in program activities (Armor et al., 1976; Bromet et al., 1977; Craft et al., 1975). Although the total effect of program type on outcome is relatively strong in the present analyses, it is primarily indirect and accounted for through the effects of treatment experiences and perceptions of the environment. The strong relationship between these program-related variables and outcome may reflect not only treatment effects but also the combined effects of the patient's motivation to recover, a more positive attitude toward the program, better functioning within the program, and a greater probability of participating in aftercare services (Craft et al., 1975; Pisani, 1969; Pratt, Linn, Carmichael, & Webb, 1977).

In comparing the importance of patient characteristics relative to program-related variables as predictors of outcome, previous studies have reported relative uniformity in outcome among programs when patient-related variables are taken into account (Armor et al., 1976; Ruggels et al., 1975). Contrary to previous findings, the combined unique effects of the program-related variables observed here are substantial. In fact, except for occupational functioning, the proportion of explained variance uniquely accounted for by program-related variables is almost equal to or greater than that uniquely accounted for by patient-related variables. These findings indicate that program-related effects may be more important than would be expected from previous research.

The results also show that 23%–40% of the total explained variance is shared between patient-related and program-related variables (see Table 3). From a different perspective, between 28% and 72% of the total effects of the patient characteristics are shared with the program-related variables. In previous research, the patient-related variables have been credited with these shared effects, leading researchers to underestimate the explanatory power of program-related variables. Given that a substantial portion of the variance is shared between these two groups of variables, researchers may have been too limited in their analyses by looking primarily for either patient or program variance. The effects of certain combinations of patient and program-related variables, such as patient-program selection and congruence effects, may be particularly important for understanding patterns of patient improvement (Pattison, 1976).

Although there are some consistencies across all four models, there are also some important differences. For example, although the intake symptom is one of the two most important predictors for three outcome criteria, it is least important in the alcohol consumption model. Apparently, the level of alcohol consumption is more strongly influenced by treatment experiences, perceptions of the treatment environment, and social background. In contrast, occupational functioning at follow-up is most strongly affected by occupational functioning at intake and much less influenced by the program-related variables. These variations indicate that the importance of program-related variables relative to background variables depends on the outcome criterion used.

Consistent with previous research on program selection, our findings show that social background is an important determinant of the type of program that a patient enters (Armor et al., 1976; Bromet et al., 1977). In addition, the findings suggest that for two patient functioning characteristics (occupational functioning and physical concomitants), the intake symptoms are also a significant determinant of program selection. These two intake symptoms are those most highly correlated with social background, and

their effects may thus reflect some underlying effects of social background.

The program is by far the most important determinant of a patient's treatment experiences and perceptions of the environment. Although the overall effect of social background on perceptions of the environment is positive here, other findings (Moos & Bromet, 1978) suggest that the effect is relatively small, and that the effects of different background variables may vary (e.g., women may perceive the environment more positively, whereas better educated patients may perceive it more negatively). Social background also has substantial indirect effects, via the program, on both treatment experiences and perceptions of the environment. These indirect effects suggest that patients with higher social background levels either enter and/or participate more actively in programs offering environmental and treatment experiences associated with better outcome. In addition, the indirect effects may reflect the fact that patients with certain background characteristics are (a) more motivated to become involved in program activities and thus receive more treatment and (b) function better within the program and thus perceive the environment as more positive.

One of the most distinctive features of the present analysis is the use of block variables. The method of determining weights that we used is one of several approaches that can be used. Alternative methods include giving the variables equal weights by averaging them, giving one or more variables a weight of one and others a weight of zero by dropping variables from the set, and using various types of factor analyses. The important point is that by grouping together a set of conceptually similar variables that are then treated as one, subsequent analyses provide a more integrated and comprehensive picture of a complicated pattern of effects.

Between 18% and 27% of the overall variance in treatment outcome is explained by all of the block variables taken together. Although this is a somewhat larger proportion of the overall variance than that accounted for in most similar studies, the majority of the variance in outcome is still unaccounted for by either patient-related or

program-related variables. Further research is needed to identify other important factors, such as the environmental resources available to patients in community settings (Bromet & Moos, 1977), that may contribute to the remaining variance. Nevertheless, the results presented here indicate that the proportion of variance in the outcome criteria uniquely associated with program-related variables is as great or greater than that uniquely associated with patient-related variables. Perhaps the most important conclusion to be derived from these results is that alcoholism treatment programs may have more substantial differential effects on outcome than previous literature has suggested. Since some of these effects are probably related to patient-program selection and congruence, it may be unwise to implement the policy of placing all patients in uniform low-cost treatment programs.

Knowledge of the effect of therapist training and experience on the outcome of treatment of schizophrenic patients is scanty. This article presents data systematically collected in the course of a controlled comparison of the effects of five different treatment methods in schizophrenia. Among the 23 outcome variables studied, there was not a single instance in which the effect of therapist experience and general clinical ability was significantly related to outcome. There appeared to be, however, differences among therapists' results that were *not* related to experience and general clinical ability, particularly in relation to the length of time that they kept their patients in hospital. Drug treatment tended to override but perhaps not entirely eliminate these effects.

Do Experienced Therapists Get Better Results?

Research evidence on this question is scanty. The vast gap in knowledge is typically filled in with a mixture of myth, speculation, anecdote, and weak research evidence, mostly relating to psychotherapy. (Betz & Whitehorn, 1956; Karon & VandenBos, 1972, 1975; Tuma & May, 1975). The notion that experience and training might influence the results of treat-

ments other than psychotherapy has been largely ignored or depreciated.

This article presents data on this issue that were systematically collected in the course of a controlled comparison of the outcome of five different methods of treatment in schizophrenia.

Background and Literature Review

The literature virtually ignores all methods of treatment except psychotherapy. Even in this area the studies are generally anecdotal or nonexperimental, with small numbers of cases and equivocal or contradictory conclusions. Strupp stated that there is some anecdotal evidence (Glover, cited in Kubie, 1956) that beginners may achieve success in psychotherapy that they are unable to equal once they have had formal training; but on the other hand, he continued, highly experienced therapists might be presumed to achieve better results, perhaps because they are more circumspect in selecting their patients (Strupp, 1958a, 1958b, 1958c, 1960). Experienced therapists are probably better aware of their own strengths and weaknesses and are not likely

The research to which this work is related has been supported in part by research grants from the State of California Department of Mental Hygiene and Grants MH 02719 and MH 04589 and Contract PH 43-66-49 from the National Institute of Mental Health, and by the Research Service of the Veterans Administration. Computing assistance from the Health Sciences Computing Facility at the Center for the Health Sciences, University of California at Los Angeles, was sponsored by National Institutes of Health Grant RR-3.

Jane A. Kirksey provided assistance in data processing and Hilda Margolis and Dona McLemore prepared the manuscript and table.

to undertake tasks that they believe they cannot tackle. Unfortunately, we have little data on well-trained, highly experienced therapists and the reasons for their presumed superior accomplishments.

An early series of studies by Fiedler (1950a, 1950b, 1951) of experienced and inexperienced therapists' description of their own attitudes and behaviors in psychotherapy is often cited in this context. However, Fiedler did not investigate whether the therapists' self-description has any bearing on actual outcome. Nor were his observations based on the treatment of psychotic patients. Thus, although Fiedler's studies focused attention on what therapists considered important in psychotherapy regardless of theoretical orientation, his data did not shed any light on the influence of therapists' level of experience on the outcome of treatment.

Carkhuff and Truax (1965) and Banks, Berenson, and Carkhuff (1967) studied changes in such characteristics of therapists as empathy, warmth, genuineness, depth of intrapersonal exploration, and positive regard in response to training and experience. Again, although the studies provided evidence that therapists' behavior during psychotherapy may be modifiable, they say nothing about therapists' characteristics relative to treatment outcome.

There is a common belief that inexperienced therapists, being relatively simple and enthusiastic, may get better results particularly with schizophrenic patients, than those who have been disillusioned by experience. Poser (1966) compared trained and untrained therapists conducting group therapy with hospitalized chronic schizophrenic patients. The untrained achieved slightly better results than the trained, and these results persisted during a 3-year follow-up. However, the trained and untrained therapists did not treat their patients at the same time, and there was a high proportion of dropouts (Rosenbaum, 1966). Barrett-Lennard (1962) compared expert counselors with nonexperts. The experts kept their clients in treatment longer and obtained more improvement at the .10 level of significance. Improvement was, however, measured by the therapists' own ratings—not independently. This could reflect the effect of self-deprecatory attitudes by the nonexperts,

enhanced self-esteem among the experts, or even the longer treatment time.

In general, the relatively few systematic though naturalistic studies of this matter (Goldberg, Schooler, Davidson, & Kayce, 1966; Cole, Note 1), point to the conclusion that psychiatrists who have completed their residency training and residents who are still at various stages of their training all obtain similar results.

With regard to drug therapy, it has been suggested that only inexperienced therapists get better results, but the findings are somewhat contradictory. In a study by Rickels et al. (1966), five board-certified or board-eligible psychiatrists treated anxious neurotic patients with psychotherapy plus placebo or with psychotherapy plus meprobamate. The combination with drug was significantly superior by a variety of criteria. Uhlenhuth, Covi, Rickels, Lipman, and Park (1972), however, reported that experienced doctors got better results with placebo, whereas the inexperienced got better results with meprobamate.

In schizophrenia, reports are also conflicting. Karon and O'Grady (1969) and Karon and VandenBos (1970, 1972) reported that patients treated by 2 experienced therapists improved more and spent less time in hospital over a 2-year follow-up than those treated by 10 inexperienced therapists: This applied whether or not drugs were used. It should not be inferred that experienced therapists got better results without drugs than with them. Indeed, well-controlled studies by Grinspoon, Ewalt, and Shader (1967a, 1967b, 1968, 1972) reported that experienced therapists obtained better results in schizophrenia with drugs plus psychotherapy than with psychotherapy alone.

Karon and co-workers also reported that when drugs were used, the inexperienced therapists kept their patients in the hospital for less time at the beginning but with less improvement in thought disorder and greater long-term hospital stay. This is, however, misleading. In fact, the patients treated without drugs spent more time (not less) in the hospital if one considers the entire period from admission to follow-up (see May & Tuma, 1970).

O'Brien et al. (1972) compared the results obtained by medical students, social workers, and psychiatrists using individual and group

psychotherapy combined with drugs for schizophrenic outpatients. There was a tendency for the medical students to get the best results, but the differences between the three groups were not statistically significant.

Clearly, there is a lack of relevant and unambiguous data in this area and a distinct need for careful studies.

Method

The data were collected in the context of a larger study in which the primary aim was to evaluate the differential effectiveness of five methods currently used in the treatment of schizophrenia. All methods are still in use today, with little, if any, difference in procedure and technique from those used then. The experimental design and procedures are described elsewhere in considerable detail (Dixon & May, 1968; May, 1968); accordingly, only certain details that are specific to the topic of this study will be presented.

Two hundred twenty-eight male and female first-admission schizophrenic patients without significant prior treatment were assigned by a stratified random method to five treatment groups: (a) individual psychotherapy alone; (b) ataractic drug alone; (c) individual psychotherapy plus drug; (d) electroconvulsive therapy; and (e) milieu, a group that received none of the above "specific" treatments but only the same level of basic milieu care given to all the other groups. The number of patients in each group was as follows: psychotherapy, 42 patients; drug, 48; psychotherapy plus drug, 44; electroconvulsive therapy, 47; and milieu, 43.

The therapists were 33 male and 5 female psychiatric residents or recently (1-3 years) graduated psychiatrists who treated an average of six patients each. Patients were assigned to their therapists on the basis of openings on a rotating roster, and each patient's treatment was supervised by a senior consultant experienced in the particular treatment to which the patient was assigned. Unless released from hospital earlier, patients were treated for a minimum of 6 months to up to 1 year before treatment was terminated.

Our analyses include data relevant to all treatment groups. It could be argued that the therapist is more central or critical when formal psychotherapy is undertaken. This is certainly a legitimate point of view, and specific analyses might have been undertaken to examine the question in this limited context. However, this study is equally concerned with the role of therapists' experience and ability in all five treatments. The core hypothesis is that therapists' experience and clinical ability may influence many of their behaviors, judgments, and decisions, which may in turn influence outcome.

Measures of Outcome

The 23 outcome measures chosen for this analysis are presented in Table 1. Additional details can be found elsewhere (May, 1968).

Table 1
Measures of Outcome

Variable	Rater
Menninger Health-Sickness Scale, post-treatment	2 independent raters (psychoanalysts)
Camarillo Dynamic Assessment Scale ^a	2 independent raters (psychoanalysts)
MMPI, posttreatment <i>F, Sc, Pa</i> , psychiatric triad	Patient
Testability, posttreatment	Psychologist
MACC Communication, Total score	Nurses
Hospital stay	
Only patients successfully discharged	—
All patients	—
Release rate ^b	—
Clyde Mood Scale, post-treatment (clear thinking scale)	Therapist
Symptom rating sheet, posttreatment, total score	Therapist

Note. MMPI = Minnesota Multiphasic Personality Inventory.

^a Consists of eight scales: Affective Contact; Anxiety Level; Ego Strength; Extent to which Environment Suffers; Insight; Motivation; Object Relations; Sense of Personal Identity.

^b Counted when patient is successful in staying out of the hospital 31 days or more.

Therapist Variables

Length of experience. A number of indices of experience were considered. These included age, number of years since internship, number of years in psychiatric residency training, and number of years of clinical experience in treating psychiatric patients.

Since treatment lasted a relatively long period of time ($M = 169.4$ days), and since the treatment phase of the study lasted several years, the indices of therapist experience were computed using the midpoint of each patients' treatment. This allows for the fact that therapists may be more or less experienced when they treat particular patients. Data describing the therapist sample on all four indices of experience were analyzed, and there were no significant differences among the treatment groups with respect to any item.

The number of years of *clinical experience in treating psychiatric patients* was chosen as the most appropriate index of "experience" for the present analysis, even

though the other three indices are also potentially relevant.¹ The length of this experience ranged from .16 to 11.65 years ($M = 3.77$, $SD = 2.87$). There was no significant difference² among treatment groups ($p = .1664$ for all patients; and $p = .3540$ for those with only one therapist). A two-way analysis of variance for the milieu, psychotherapy alone, psychotherapy plus drug, and drug-alone groups examined the differences in therapist psychiatric experience between the two groups that received psychotherapy and those that did not receive psychotherapy. This resulted in a p value of .0281 for all patients, and $p = .0334$ for those with only one therapist. This reflects a deliberate design bias in favor of psychotherapy, in that, as pointed out in an earlier publication (May 1968), therapists with less than 6 months of experience were not assigned to treat patients in psychotherapy.

Therapists' general clinical ability. Every 6 months a rating was made by a senior psychiatrist of the therapist's general clinical ability relative to others of a comparable level of training. The rating made on the date closest to the midpoint of each patient's treatment was used in the present analysis. No significant differences were found between the treatment groups in terms of ratings of therapists' general clinical ability ($p = .3006$ for all patients, and $p = .2303$ for those with only one therapist).

Patient Variables

Seven patient covariates were used to adjust for initial pretreatment differences among patients: presence or absence of precipitating stress; intensity of such stress relative to onset of illness; duration of psychotic disorder; nurses' pretreatment ratings of cooperation on the Movement, Affect, Communication, and Cooperation (MACC) scale (Ellsworth, 1957; Ellsworth & Clayton, 1959); psychoanalysts' pretreatment ratings of affective contact, best level ever attained (May & Dixon, 1969); age at onset of any symptoms; and pretreatment level on the outcome measure under study. Ratings on the Menninger Health-Sickness Scale (Luborsky, 1962) were used to adjust hospital stay and release rate, since no initial level on these measures is obviously available or applicable.

Statistical Analysis

General. An analysis of covariance was performed in which the criterion score of any particular patient was taken as comprising portions of variation associated with: (a) therapist's years of experience, (b) therapist's general clinical ability relative to peers, (c) drug treatment, (d) pretreatment patient variables, and (e) other unknown parameters (error).

Covariance runs. The covariates (i.e., patient, therapist, and drug covariates) were examined separately, first for all patients and then for patients with one therapist (the majority of cases). Wherever there were two therapists, the data relate to the patient's major therapist, that is, the one who treated the patient for the longest period of time.

Interpretation. The analyses examined whether there were differences in outcome among therapists and to what degree these differences could be attributed to the specified covariates.

1. Are the differences in outcome attributable to a particular covariate or group of covariates; that is, is the regression slope significantly different from zero?

2. Are there differences in outcome among therapists before and after adjusting out the covariate; that is, are the therapist cell means significantly different?

The probability of residual differences among therapists after adjusting out the covariate is compared with the probability before covariance adjustment.

Results

Was Therapist Experience Significantly Related to Treatment Outcome?

Among the 23 outcome variables, there was not a single instance in which the regression slopes for the effects of therapist experience and general clinical ability were significantly different from zero, whether for all cases or for those with only one therapist.³ Indeed, the relationship reached borderline significance for only one outcome variable, length of stay for patients successfully released only, not including the failures ($p = .0875$). This relationship was nonsignificant ($p = .6123$) when examined for cases with only one therapist. Our inclination is to discount this lone marginal finding as a chance occurrence in the midst of a great number of insignificant p values.

Were There Significant Differences in Outcome Attributable to Therapist Factors Other Than Experience and General Clinical Ability?

Length of stay. After adjusting for the effects of therapist experience and general clinical ability, there were significant differences among therapists in the length of time that they kept their patients in hospital. The adjusted therapist means were significantly different for length of hospital stay for patients who were successfully released only, not including the failures ($p = .0131$ for all cases,

¹ Data on all indices can be made available to investigators on request.

² In this article the term *significant* is used if $p < .05$ and *borderline significance* if $.10 > p > .0501$.

³ To save space no detailed tables will be presented here, only p values will be presented as appropriate.

and $p = .0239$ for cases with only one therapist). For length of stay for all patients, including the failures, $p = .0927$ for all cases and $p = .0362$ for cases with only one therapist. These differences in patients' hospital stay could not be attributed to their therapist's experience in the treatment of mental illness, to ratings of their general clinical ability, or to the seven patient covariates examined, since the differences remained significant even after adjusting for patient differences on these covariates. (After adjustment for length of stay to successful release, $p = .0134$ for all cases, and $p = .0234$ for cases with only one therapist. For length of stay including the failures, $p = .0733$ for all cases, and $p = .0369$ for those with only one therapist.)

There was some evidence that these therapist-related differences in length of hospital stay were partly, but not entirely, related to whether or not the patient was given drug treatment, since the significance levels were sharply reduced when further adjustment was made for drug treatment. (For only the patients who were released, the significance level changed from .0134 to .0837 for all cases; p changed from .0234 to .1662 for those with only one therapist. For all cases including the failures, the p levels changed from .0927 to .2263 and from .0363 to .1534, respectively.)

Other outcome measures. After adjusting for the effect of therapist experience and clinical ability, there were significant or borderline differences among therapists' results for only 1 of the other 21 outcome measures, the Minnesota Multiphasic Personality Inventory *Pa* scale (Dahlstrom & Welsh, 1960; Hathaway & McKinley, 1943) ($p = .0467$ for all cases, and $p = .0349$ for those with only one therapist). This should probably be dismissed as chance occurrence among so many analyses.

Again, the significance of the difference is reduced if further adjustment is made for whether or not drug treatment was given ($p = .1546$ for all cases, and $p = .1458$ for those with only one therapist).

Discussion

These results are presented with some hesitation for we are mindful that some may take them as definitive findings from an experiment

in which both therapists and patients were randomly assigned to a given treatment, which they were not; as applying to all types of mental disorder besides schizophrenia, which they do not; and as applying to the (small and select number of) highly experienced persons who specialize in the treatment of schizophrenia, which they do not. They do deserve some credence, however, as an epidemiologic report from a carefully controlled study with a moderate but carefully defined and measured range of therapist experience, in which patients were randomly assigned to treatment and therapists were assigned from a rotating roster, with no self-selection of patients.

Within these limitations, some of the findings encourage further work on the relationship between therapist characteristics and the outcome of their treatment of schizophrenic patients. The findings suggest that there are possible differences among therapists in the results they obtain. Such differences may, however, bear little relationship to therapist experience or general clinical ability (as defined and within the range sampled in this study) or to the usual patient prognostic factors. They may turn out to be related more to other therapist characteristics, perhaps of personality, sophistication in the use of various treatment strategies and activities, and ability to handle paranoid or hostile attitudes.

The point must be made, however, that these findings do not necessarily mean that training and experience make no difference at all. Obviously an inexperienced and unsupervised or inept therapist could abuse or misuse any form of treatment, whereas a talented, versatile, and highly experienced therapist could optimize its value. A more likely interpretation of our data is that the kind of intensive supervision that our therapists received in addition to the usual teamwork approach to treatment in general may have been sufficient to compensate for any differences in results that might otherwise have occurred due to therapists' factors.

In future work, the effect of drug treatment must be carefully taken into account, since this powerful form of treatment seems to override or compensate for differences in outcome that might otherwise occur among therapists.

It is concluded that future research in this area should focus on identifying *specific* therapist characteristics other than general clinical experience and general clinical ability (as defined in this study) that relate to *specific* outcome characteristics. In this way progress might be made toward eventually matching therapist and patients *when a specific outcome characteristic is desired*. Perhaps, therefore, the research questions should be rephrased in more sophisticated form: At what point for each particular type of clinical problem and for each particular type of treatment do training and experience begin to influence treatment results, and is there a point of diminishing returns? What is the shape of the experience/effectiveness curve? Is there an optimum cost-effective point in training and experience?

It may be that the future will bring rigorous experiments designed to answer such questions. At this time, however, we are forced to rely on less definitive material.

Received October 3, 1977

An MMPI Scale to Separate Brain-Damaged From Functional Psychiatric Patients in Neuropsychiatric Settings

Charles G. Watson and Duane Plemel
Veterans Administration Hospital, St. Cloud, Minnesota

An empirical Minnesota Multiphasic Personality Inventory scale was developed to separate brain-damaged from functional psychiatric patients. It consisted of 56 items, which significantly differentiated organic and functional groups in a psychiatric hospital and was named the Psychiatric-Organic (*P-O*) scale. Upon cross-validation it was found capable of separating organics from process and reactive schizophrenics, alcoholics, and neurotics, as well as patients with character disorders and affective psychoses. Additionally it was found that by using the scale in combination with a traditional brain-damage test (the Benton Visual Retention Test), better discrimination could be achieved than was possible with either measure alone. The comparative probabilities of functional and organic diagnoses for various *P-O* scale ranges are presented.

The literature on the separation of brain-damaged from nonorganic psychiatric patients via measures of ability is generally unencouraging. Attempts to differentiate organics from schizophrenics with such instruments as the Halstead battery (Watson, Thomas, Andersen, & Felling, 1968); the Trail-Making Test (Brown, Casey, Fisch, & Neuringer, 1958); the Critical Flicker Fusion Test (Watson, Thomas, Felling, & Andersen, 1969); the Bender-Gestalt; and the Graham-Kendall Memory-For-Designs Test (Watson, 1968) have often met with failure. Somewhat more success has been achieved by investigators using personality measures to separate the two groups (Russell, 1975; Watson, 1971; Watson & Thomas, 1968). The Minnesota Multiphasic Personality Inventory (MMPI) Schizophrenia-Organicity (*Sc-O*) scale, which was developed for that purpose (Watson, 1971), has proven to be of value and has been cross-

validated successfully in at least six settings (Ayers, Templer, & Ruff, 1975; Holland, Lowenfeld, & Wadsworth, 1975; Watson, 1971; Andersen, Felling, & Seitz, Note 1; Gilbertstadt, Note 2). In addition, personality and ability measures have been combined to enhance separation of organic and schizophrenic patients (Watson, 1973).

There is also reason to believe that the separation of organics from other functional disorders is problematic as well. Watson, Davis, and Gasser (1978) found that such commonly used instruments as the Halstead Category; Benton Visual Retention; Smith Digit Modality; and Wechsler Adult Intelligence Scale (WAIS) Digit Span, Block Design, and Object Assembly tests are of little value in the differentiation of psychiatric hospital organics from depressives. These findings suggest that research designed to develop a personality scale capable of separating organics from individuals suffering from all types of functional disorders is needed. Although one might have hoped that the *Sc-O* would separate nonschizophrenic functional groups from organics, Watson's (1973) article indicates that it does not, and that a new scale is needed. Accordingly, the research program described here was formulated to develop an MMPI scale for that purpose.

This research was supported by the Veterans Administration Medical Research Service. The authors are indebted to Betty Gasser, Allan Schaefer, Lyle Jacobs, Teresa Kucala, Gail Bamber, and Ed Medeck for their contributions to this research.

Requests for reprints should be sent to Charles G. Watson, Research Service, Veterans Administration Hospital, St. Cloud, Minnesota 56301.

Table 1
Mean Age, Education, and Estimated Full
Scale IQ in Scale-Construction Groups

Variable	Brain damaged	Psychiatric	t
Age	48.3	40.0	3.71*
Education	10.1	11.3	2.66*
Estimated IQ	96.0	109.0	4.75*

* $p < .01$.

Method

Scale Construction

Patients referred to the Psychology Service at the St. Cloud (Minnesota) Veterans Administration Hospital specifically for evaluation of possible brain damage served as subjects for item selection. The brain-damaged group consisted of 40 individuals who were eventually given diagnoses of organic brain syndrome, and whose physician, ward nurse, and psychologist all agreed on the basis of history, laboratory, and/or clinical findings that brain damage was present. (The raters were instructed to make their assessments independent of psychological test data.) The controls were 60 patients who had received functional diagnoses and whose ward physician, psychologist, and nurse agreed that clinically detectable brain damage was not present. Only patients under 60 years of age were included. When more than one testing was available, the MMPI scores taken at the time point closest to referral were used. Only potential subjects with MMPIs taken within 1 month of referral were included.

As might have been expected, the groups differed significantly on mean age, education, and Henmon-Nelson-based estimate (Watson & Klett, 1975) of WAIS Full Scale IQ. These means are reported in Table 1. According to the patients' clinical files, the causes of brain damage in the organic group were alcohol (26), trauma (8), cerebrovascular accident and multiple sclerosis (2 each), and presenile dementia and brain surgery (1 each). The diagnoses of the controls were alcohol addiction (35); schizophrenia (8); depressive neurosis (7); schizoid personality and habitual excessive drinking (2 each); and drug intoxication, adjustment reaction to adult life, anxiety neurosis, episodic excessive drinking, passive-dependent personality, and inadequate personality (1 each).

Results

Chi-square tests were then run on each MMPI item to determine which items significantly differentiated the two groups. Fifty-six were significant at the .05 level and were, collectively, labeled the *Psychiatric-Organic (P-O) scale*.

The (Form R) items selected, and the directions consistent with an organic diagnosis, were 3, 95, 96, 132, 133, 137, 170, 198, 207, 264, 287, 310, 329, 392, 450, 498, 510, 520 (True); 9, 21, 38, 41, 51, 61, 86, 90, 106, 129, 156, 158, 168, 179, 187, 191, 192, 195, 212, 217, 224, 225, 226, 266, 277, 284, 305, 307, 308, 317, 325, 366, 372, 425, 468, 511, and 540 (False). Eighteen items were keyed "true" and 38 "false."

Scale Characteristics

The internal consistency of the scale was assessed via Ebel's (1951) intraclass correlation technique. It yielded coefficients of .90 for the organics and .68 for the controls. This disparity is puzzling. It may reflect the confusion commonplace in the test-taking performance of psychiatric patients or the heterogeneity of the controls.

A moderate amount of item overlap existed between *P-O* and the other scales. The percentages of the items on the various clinical scales that also appear on *P-O* are detailed in Table 2. Since 10% of all the MMPI items are included on *P-O*, meaningful overlap is represented by the extent to which the percentages exceed 10%. The table reveals that none of the overlaps were high, the largest being only 20%. The greatest overlaps appeared between *P-O* and the Lie (*L*), Psychasthenia (*Pt*), and Schizophrenia (*Sc*) scales. The overlap with Social Introversion (*Si*) was strikingly low.

Correlations were run between the *P-O* scale and each of the MMPI validity and clinical scales for the scale construction samples. These correlations, as well as those of the *P-O* scale with the *Sc-O* scale developed by Watson (1971) to separate organics from schizophrenics, did not differ significantly from group to group. Therefore, the samples were pooled; the correlations for the combined groups are also presented in Table 2. The largest correlations appeared on the validity scales and on *Pt* and *Sc*. Lesser significant correlations appeared between *P-O* and all other MMPI scales studied except Hypochondriasis (*Hs*) and Hysteria (*Hy*). Despite the existence of a slightly higher than chance quantity of overlap between *P-O* and both *Hs*

Table 2
 Percentages of Clinical/Validity Scales Consisting of P-O Items, and Their Correlations with P-O

MMPI scale	Overlapping items		Total	Scale length in items	%	r
	Same direction	Opposite direction				
<i>L</i>	3	0	3	15	20	.55*
<i>F</i>	0	2	2	64	3	-.61*
<i>K</i>	3	1	4	30	13	.62*
<i>Hs</i>	3	1	4	33	12	.08
<i>D</i>	3	5	8	60	13	-.36*
<i>Hy</i>	4	4	8	60	13	-.01
<i>Pd</i>	0	9	9	50	18	-.49*
<i>Mf</i>	1	7	8	60	13	-.52*
<i>Pa</i>	0	4	4	40	10	-.57*
<i>Pt</i>	0	9	9	48	19	-.61*
<i>Sc</i>	2	11	13	78	17	-.57*
<i>Ma</i>	0	6	6	46	13	-.35*
<i>Si</i>	0	1	1	70	1	-.47*
<i>Sc-O</i>	1	6	7	80	9	.54*

* $p < .05$.

and *Hy*, the correlations between *P-O* and those two scales were low. These low correlations may reflect the fact that somatic symptoms are moderately common in both organics and psychiatric patients. The size and breadth of the correlations with those MMPI scales are encouraging, since they suggest that the new scale reflects functional pathology of many sorts. Also encouraging was the presence of a significant correlation between the *P-O* and *Sc-O* scales, both of which were designed to separate organics from functional, although somewhat different, psychiatric samples.

P-O was also moderately correlated with age ($r = .30$); this coefficient can be interpreted as indicating that the scale capitalizes on the tendency for brain-damaged patients to be older than functional patients and makes use of the contribution of age-related personality factors to the discrimination of the two groups from one another.

Cross-Validation

The scale was cross-validated twice with samples drawn from the St. Cloud Veterans Administration Hospital. In the first, the scale was administered to 100 patients, none from the scale construction samples, referred for evaluation of possible brain damage. After testing had been completed, the patient's

physician, nurse, and ward psychologist were consulted. Only those patients in whose cases all three agreed on whether the patient was brain damaged or not were used in the study. *P-O* scores were not available to the raters. Scores of 40 organics and 60 controls were thus collected. As described in their clinical files, the causes of brain damage were alcohol (26 cases); trauma and alcohol (4); trauma, infection, and cerebrovascular accident (2 each); and Wilson's disease, cerebral arteriosclerosis, Sydenham's chorea, and unknown cause (1 each). Preadministered MMPIs were then collected from the subjects' Psychology Service files and compared. The mean *P-O* score of the organics was 31.6 ($SD = 7.7$), whereas that for the controls was 25.4 ($SD = 9.5$). The difference was significant, $t(98) = 3.43$, $p < .005$. This finding was interpreted as being very encouraging, since the samples drawn consisted of subjects in whose case the organic diagnosis was sufficiently problematic to require special evaluation.

As a further test, the scale was scored on a sample of recently admitted/readmitted males under 60 at the St. Cloud Veterans Administration Hospital. According to their clinical file diagnoses, these subjects consisted of 30 organics, 55 neurotics, 98 alcoholics (men with diagnoses of alcohol addition or habitual excessive drinking), 56 character disorders

Table 3

Mean P-O Scores, Standard Deviations, and *t*s for Differences Between Organic and Functional Groups

Sample	<i>M</i>	<i>SD</i>	<i>t</i>
Organic	33.2	6.5	—
Process	26.4	9.3	3.89**
Reactive	27.2	8.2	3.59**
Neurotic	27.2	9.1	3.50**
Alcoholic	27.2	8.8	4.04**
Character disorder	26.8	9.1	3.71**
Affective psychosis	26.8	10.2	2.29*

* $p < .05$.

** $p < .001$.

(men with diagnoses of personality disorder or sexual deviancy), 17 affective psychotics, and 105 schizophrenics. The schizophrenics were split into process and reactive groups by the Ullmann and Giovannoni (1964) Process-Reactive Scale. Those 54 who produced scores of 13 or above were characterized as process, whereas those 51 with scores of 12 or less were classified as reactives. As described in their clinical files, the causes of brain damage in the organic sample were alcohol (10); trauma (8); both trauma and alcohol (3); and Huntington's chorea, atrophy, arteriosclerosis, Wilson's disease, abscess, presenile dementia, cerebrovascular accident, multiple sclerosis, and tumor (1 each). These diagnoses were also made without the benefit of P-O scores. An *F* test run between the means of the seven groups was significant, $F(6, 354) = 2.36$, $p < .05$, and *t* tests were run between the organics and each of the functional groups. These are displayed in Table 3. The reader will note that the mean

for the organics was 33.2, whereas those for the six functional groups ranged from 26.4 to 27.2. All *t*s were significant at at least the .05 level, and five of the six were significant at the .01 level.

P-O Score Interpretation

Although the *t*s are encouraging, the relatively high standard deviations suggest that P-O scale scores between the means of the organic and functional groups are probably of dubious value in the separation of organic from functional patients. Therefore, single cutting scores are not presented here. Instead, distributions of the P-O scores for the 70 organics and 391 functional patients in the two studies were plotted for the purpose of identifying the relative probabilities of organic and psychiatric diagnoses among scorers at various P-O scale levels. These percentages, which are presented in Table 4, allow the diagnostician to make a "better odds" interpretation of P-O scores. For example, given equal base rates, scores between 15 and 20 were 3 times more common among functional than organic patients. Interpretation of these scores, of course, should be tempered by a consideration of local base rate. With even base rates, scores below 27 are more typical of psychiatric than organic patients, whereas those above 27 are more common among brain-damaged patients. Scores between 27 and 32 contribute little to diagnostic differentiation.

Combined Use of P-O and Ability Measures

In at least two studies (Watson, 1978; Watson et al., 1978), the use of personality

Table 4

Percentages of Organic and Functional Subjects at Various P-O Score Ranges and Odds for Organic/Functional Diagnoses

P-O range	Percentages		Odds	
	Organic	Functional	Organic	Functional
39+	25	9	2.78	1
33-38	30	21	1.43	1
27-32	24	21	1.14	1
21-26	15	23	1	1.53
15-20	5	16	1	3.20
0-14	1	10	1	10.00

and ability measures in concert substantially improved on the discriminative power made available by either alone. Following the technique used in those studies, the scores of the 70 organics and 391 controls in the two cross-validation studies on the *P-O* scale and on the Benton Visual Retention Test (BVRT) error scores were graphed on a scatterplot. (The BVRT was used because earlier research [Watson, 1965; Watson, 1968; Watson et al., 1968, 1969] has suggested that it is better able to separate organic from schizophrenic patients than most other visual/motor tests for brain damage.) A straight line was then drawn in such a fashion as to maximize discrimination between the two groups (see Figure 1). This discrimination line yielded hit rates of 69% and 75% for the organic and the control samples, respectively, and an (unweighted) average hit rate of 72% over the two samples. These hit rates are somewhat better than the best that could be obtained using either *P-O* (organics, 77%; controls, 52%; $M = 64.5\%$; cutoff = 27.5) or BVRT (organics, 60%; controls, 77%; $M = 68.5\%$; cutoff = 9.5) scores alone.

Discussion

The results of the cross-validations are generally encouraging. They indicate that the *P-O* scale can be used with moderate accuracy to separate organics from psychiatric patients and that it can improve the prediction available from at least one ability-oriented test. Additionally, the item overlaps with the 13 MMPI validity and clinical scales are low enough to indicate that it makes a contribution to assessment that is not available from any one of those scales.

Additional cross-validations from other laboratories are needed. In particular, the utility of the scale with female samples needs assessment; earlier research (Watson, 1971) indicated that the *Sc-O* scale was of no value in separating organic and schizophrenic females. It appears that the personality correlates of brain damage may vary with sex, and the *P-O* scale's validity as a differentiator of female organic and functional patients should not be assumed.

It is particularly important that readers not

Figure 1. Optimal cutting line for separation of organic and functional patients.

view the *P-O* scale as a technique for identifying brain damage in nonpsychiatric settings. There is no evidence that it will separate organics from psychiatric normals or medical patients, and earlier research has indicated that our *Sc-O* scale does not separate organics from chronic pain or spinal-cord injury patients (Sand, 1973).

"Biosyntonic" Therapy: Modification of an Operant Conditioning Approach to Pedophilia

J. Dennis Nolan and Curt Sandman
Ohio State University

A modified operant conditioning approach for treating sexual behavior problems, termed "biosyntonic" therapy, is introduced. Following physiological diagnosis, a child molester was successfully taught to alter his inappropriate physiological arousal to prepubescent females without disrupting his arousal to adult females. In addition to eliminating his child molesting, the procedures also improved the correspondence between his physiological and verbal response patterns and decreased his anxiety. The treatment remained successful at a 6-month follow-up.

Deviant sexual behaviors have been much more resistant to traditional treatments than other behavioral problems (Bieber, 1962). Even aversive conditioning approaches, which seem to be the treatment of choice for some deviant sexual behaviors (O'Leary & Wilson, 1975), are not as effective for sexual behavior problems as for other behavior problems. In fact, radical surgical techniques such as castration have been proposed seriously as the only adequately reliable intervention for such psychopathic sexual behaviors as pedophilia (child molesting).¹ In this study we report the successful application of an approach we have labeled "biosyntonic" to a formerly intractable sexual behavior problem. This approach offers a promising alternative that does not preclude all sexual behavior. It attempts to bridge the hiatus between so-called mental and physical aspects of human behavior generated by traditional approaches to understanding and modifying behavior.

Most forms of psychotherapy rely exclusively on the client's verbal behavior (in most cases the real concern is with some internal

state or "mental" activity) and, except in very rare situations, completely ignore physiological processes. The behaviorally oriented therapist often relies on the observation of behavioral changes in the client, but again, without regard to the physiological state of the organism. Conversely, although scattered reports of the behavioral consequences of conditioning physiological responses exist, for the most part they deal with behaviors of only indirect practical relevance (Beatty, Greenberg, Deibler, & O'Hanlon, 1975; Blanchard & Young, 1973; McCanne & Sandman, 1974). Biofeedback approaches have been partially successful in the treatment of some physical disorders (e.g., functional auricular arrhythmias; Weiss & Engel, 1971), especially when the modified response system is part of the symptom at issue. Attempts to characterize the subtle yet pervasive physiological processes underlying certain behaviors and diagnostic classes have also been reported (Greenfield, Katz, Alexander, & Roessler, 1963; Lacey, 1959; Lacey & Lacey, 1970; McCarron, 1973; Sandman, 1975; Shagass & Schwartz, 1962), but no attempts have involved all of these perspectives

The authors' contributions were complimentary and of equivalent importance. Hence, order of authorship was determined by a coin toss.

Requests for reprints should be sent to either J. Dennis Nolan or Curt Sandman, Department of Psychology, Ohio State University, Columbus, Ohio 43210.

¹ A superior court judge in San Diego, California, recently authorized castration (as an alternative to life imprisonment) of a child molester. The judgment was based on a psychiatrist's report that the molester was aware of what he was doing and could not be cured of his perversion.

in the treatment of serious human behavior problems.

Rationale for Modification

In most aversive conditioning approaches to modifying undesirable behavior, the conditioning process involves pairing an aversive stimulus with the target stimulus (e.g., O'Leary & Wilson, 1975). For example, in the case of a pedophile, electric shock might be systematically paired with slides of children or perhaps with the patient's own imagery involving a child. In more sophisticated uses of such procedures, delivery of the aversive stimulus may be on a variable rather than a fixed schedule (e.g., Marks & Gelder, 1967), but the delivery of the aversive stimulus is invariably contingent on the presentation of the target stimulus, not on the patient's physiological response to that stimulus. Hence, in the usual aversive conditioning paradigm, shock is delivered regardless of whether (or when) the patient's response to the target stimulus is inappropriate. In the approach described in this study, the reinforcing stimulus is delivered only when the patient's physiological response to a target stimulus suggests that he is aroused. This approach insures that conditioning is problem specific yet does not depend directly on the patient's verbal report of his arousal. The reinforcing stimulus can be delivered immediately and accurately at the very onset of the physiological response without relying on either the accuracy or the speed of the patient's verbal report. Even if the verbal report were considered accurate, it probably would not occur as quickly or as reliably as the physiological response. Any resulting delay or unreliability of the delivery of the reinforcing stimulus could weaken the effectiveness of the conditioning procedure. The "biosyntonic" approach avoids both of these potential problems. An additional advantage of this approach is that the reinforcing stimulus can be initiated or terminated *during* the presentation of a target stimulus whenever changes in the patient's physiological response warrant such action.

We have introduced the term "biosyntonic" to refer jointly to the synchrony among physiological systems and to the correspondence

between thoughts or attitudes and the physical state of the organism. That is, we are concerned with the syntony among verbal (mental), physiological, and gross behavioral aspects of the human experience. A major assumption of this approach is that attitudes, emotions, and behavior are intimately related to the physiological state of the organism. The physiology is not considered a mere passive reflection of the psychological state but rather an active (though probably incomplete) determinant of attitudes, emotions, motives, and beliefs. Thus, it is our assumption that behaviors and all their attendant psychological constructs are represented by distinct physiological patterns, each pattern relating to a different psychological state. To further complicate the matter, a sizable body of research (Hein, 1969; Lacey & Lacey, 1958; McCanne & Sandman, 1975; Sandman, 1975) suggests that such patterns are highly idiosyncratic to both persons and situations. From such a "biosyntonic" perspective, then, the work of the therapist is to carefully identify (diagnose) the physiological state of the individual in specific situations before attempting to intervene. Once the relationship between mental and physical activity has been observed in nonproblem areas, then the therapist can approach the problem areas searching for evidence of disharmony in this relationship. The goal is to target physiological systems in the problem area that appear to be disparate with the patterns of responses in the more normal areas of the client's life. Once a physiological system has been observed to be abnormal in the sense described herein, the "biosyntonic" position implies that by changing the physiological pattern, the client can be helped to experience a change in attitude or emotions or both and, concomitantly, to experience a change in overt behavior. Although several studies conducted in our laboratory with normal subjects support this view (Baker, Sandman, & Pepinsky, 1975; Kaiser & Sandman, 1975; McCanne & Sandman, 1974), the present case study presents the first successful clinical test of our thesis.

Case Report

Mr. J., a 32-year-old blue-collar worker, had a history of numerous sexual experiences

with children (nearly all females) dating from his teens. Fearful of the personal and legal consequences of the discovery of his experiences with a female child, he consented to the procedures described below as a last resort. Traditional approaches had been tried without success.

Assessment

Preliminary diagnostic information indicated extreme sexual attraction for prepubescent females, although Mr. J. maintained an adequate sexual relationship with his wife. An extensive pretreatment physiological assessment was conducted by attaching electrodes for the measurement of heart rate, peripheral vasomotor activity, respiration, and skin potential. Mr. J. was reclined in a comfortable chair and viewed a standard sequence (Sandman, 1975) of pictures presented on a screen in front of him. The series included sexually arousing, neutral, and highly distressing (e.g., mutilated corpses) slides. He rated each of them on a 9-point pleasure-stress scale. Physiological recording was done with a Grass Model 7B polygraph equipped with appropriate preamplifiers and driver amplifiers that were housed in the adjacent control room.

Mr. J. exhibited differential physiological responses to pleasurable, neutral, and unpleasurable stimuli only in heart rate. His vasomotor and electrodermal responses were not differentially responsive to stimuli of different pleasure ratings. Hence, we hypothesized that the cardiovascular response system could be a significant component of his total response to pleasurable stimuli. We therefore focused on heart rate in a discriminative conditioning paradigm used throughout 16 sessions; the conditioning was designed to alter his physiological responses to female children without disrupting his responses to adult females.

Initially, four sets (male and female adults and male and female children) of six stimuli each were chosen. Mr. J. was asked to bring in pictures of preadolescent girls that he found arousing to varying degrees. Very prevalent among the most arousing stimuli were pictures taken from mail-order catalogues of girls modeling underwear. Upon request he also brought

comparable pictures of preadolescent boys, though he claimed none of these were highly arousing. He selected adult male and female stimuli from a group of slides available at the treatment center. Mr. J. rated each of the stimuli in each of the four sets in terms of his perceived sexual arousal to them. Ratings were based on the 9-point pleasure-stress scale described earlier.

The most striking feature of his physiological response pattern to these four sets of stimuli was the extremely elevated heart rate response to the pictures of the semiclothed female children. However, unlike his response to nude adult females, his verbal report of arousal to the slides of children was not consistent with his physiological response to them² (Figure 1A). Neither his verbal nor his physiological responses suggested arousal to male children or male adults. Therapy was therefore designed to accomplish both the reduction of the inappropriate arousal to female children and improvement of the congruity between the patient's verbal and physiological responses to such children.

Results of Treatments

In Phase 1 of the treatment, heart rate increases during the presentation of slides of young female children were punished by the administration of electric shock (4–6 mA) to Mr. J.'s index finger. Heart rate was detected by level detectors (BRS Digibit Logic Modules) with preset criteria. The detectors were connected to a stimulator (Chicago-Nuclear) that automatically delivered electric shock when Mr. J.'s heart rate exceeded the criterion. The criterion for heart rate was the 90th percentile of resting heart rate range. Periodic adjustments were made for basal heart rate shifts. As illustrated in Figure 2a, throughout the first session there was a substantial difference between the heart rate dur-

² An analytic interpretation of this finding could be that the patient is employing a psychological defense, denial or repression, and thereby is not "able" to consciously report his true feeling about the stimuli. Lazarus (1968) has demonstrated that the process of denial can even effect the physiological responses to stimuli.

Figure 1. Correlation coefficients between verbal ratings of arousal and heart rate during presentation of slides and mature and immature females (1A) before and (1B) after "biosyntonic" therapy. (Data are for the first eight heartbeats of each stimulus presentation.)

ing presentation of slides of female children and the rate during slides of adult females ($p < .05$ for beats 1 and 6; $p < .01$ for beats 7 and 8).⁸ By the second session, however, the abnormal response to the children had been eliminated (Figure 2b; no significant differences). Responses to the two male stimulus classes remained unchanged, and we therefore discontinued presentation of slides of males at this point. To guard against the possible effects of habituation, during the third session new slides of semiclothed female children were introduced without compromising the effects of therapy. At the end of this session, Mr. J. reported the first incident in which he experienced a sharp pain in his index finger (where the shock had been delivered) whenever he felt the beginning of what he termed his "automatic arousal" response to observing preadolescent girls in provocative positions during his daily activities. The effect of this conditioned pain response was the abortion of the automatic arousal response and the complete elimination of the overt child molesting that had previously occurred under

such conditions. He also reported that he could no longer find pictures of young girls that were sexually arousing in any of the catalogues or magazines he had used previously. This report was considered a very positive sign, but continued treatment was nevertheless considered essential. Therefore, we introduced a new and potentially more provocative set of slides of a female child in poses ranging from fully clothed to nude. Mr. J.'s dramatic heart rate response to the very provocative stimuli is illustrated in Figure 2c. Our Phase 1 procedures were again effective in reducing Mr. J.'s responses to those powerful stimuli (Figure 2d), but they did not eliminate the responses ($p < .05$ for beats 6 and 7; $p < .01$ for beats 1, 2, 3, 4, 5, and 8). A more powerful conditioning technique was needed.

In Phase 2 we attempted to enhance the

⁸ One-tailed t tests were performed on beat-by-beat differences in heart rate during slides of adult females versus slides of young girls. The p values are listed for all statistically significant results.

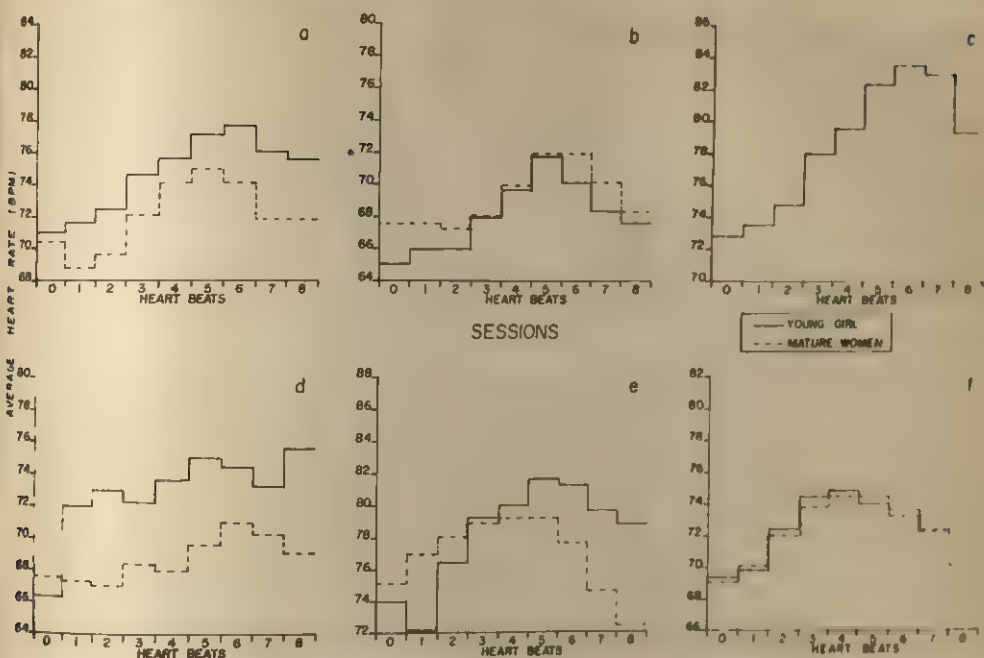

Figure 2. Heart rate patterns during presentation of provocative pictures of mature and immature females through the course of treatment. (Data are for the first eight heartbeats of each stimulus presentation.)

discrimination by providing positive reinforcement (monetary reward based upon the amount of time Mr. J. kept his heart rate above criterion) for appropriate heart rate responses (i.e., responses that were consis-

tent with the responses of the diagnostic sessions) to the adult females while continuing punishment for heart rate increases to pictures of the child. In Figure 2e it is evident that the pervasive effect of the provocative

Figure 3. Heart rate response to prepubescent females before and after "biosyntonic" therapy. (Data are for the first eight heartbeats of each stimulus presentation.)

Figure 4. State anxiety scores for each session before and after "biosyntonic" therapy.

child had diminished and the acceleratory response had changed by 9 beats. However, even though this effect was dramatic and substantial, we were still somewhat dissatisfied with the discrimination ($p < .05$ for beat 6; $p < .01$ for beats 7, 8). It seemed as if the aversive conditioning procedures, though initially essential in establishing the reinforcement contingencies, also might have contaminated both the heart rate response and the discrimination. The usual response to shock, for example, is heart rate acceleration. In order to eliminate this possible contamination, we introduced Phase 3.

In Phase 3, positive reinforcement remained contingent upon heart rate acceleration to adult females, but positive reinforcement was also presented for *inhibition* of the acceleratory heart rate response to slides of the young girl. This procedure proved highly effective within two sessions, as illustrated in Figure 2f (no significant differences). We continued the Phase 3 procedure for two additional sessions with no incidents and terminated treatment after arranging for follow-up evaluations.

At the end of the therapy the patient's extreme heart rate accelerations to pictures of young female children had been eliminated

(Figure 3),⁴ and the correspondence between his verbal and physiological response patterns was normalized (Figure 1B). He had not assaulted a child for several months (compared with a history of almost weekly incidents).

In addition to the physiological data and the patient's verbal reports, state anxiety (Spielberger, Gorsuch, & Lushene, 1969) data were collected for each session, both before and after treatment. There was a consistent decrease in anxiety over the 16 sessions,⁵ with a marked drop at Session 12, apparently reflecting the elimination of the shock contingency (Figure 4).

Follow-Up

Six months after treatment was terminated, Mr. J. reported that he had not experienced

⁴To equate starting heart rate, 7 beats/minute were subtracted from the rate for each "before" beat. The t tests on the adjusted comparisons were statistically significant for beats 3, 4 ($p < .05$), and 5 ($p < .01$).

⁵Using $SD = 14$, based on norms given by Spielberger, Gorsuch, and Lushene (1970), this decrease was statistically significant, $t(15) = 2.78$, $p < .01$.

any incidents of child molesting. He remarked that when he was in a situation formerly considered provocative, he still experienced some pain in his index finger. Of more importance, he has consciously avoided compromising situations, indicating that he is able to control his behavior much more efficiently than before "biosyntonic" therapy. It was of special interest to learn that Mr. J. attends X-rated movies at a far higher rate than he did before therapy. He had been to only one such movie before therapy, but in the first 6 months following therapy, he attended about nine. Whether this is the direct consequence of positively reinforcing his physiological responses to nude adult women in our procedure, or a compatible symptom substitution, is uncertain. In any case, the result is that a socially condoned activity has apparently replaced his psychopathic and deviant behavior.

Discussion

The new procedures reported here suggest a dramatically successful alternative to the treatment of an intractable psychopathic sexual behavior problem. The important procedural distinction between the "biosyntonic" therapy approach and other conditioning approaches is that in "biosyntonic" therapy the delivery of reinforcement is contingent on the appropriateness of the patient's physiological response to a stimulus and not merely on the presentation of the stimulus. In the present case, "biosyntonic" therapy insured that the conditioning was problem specific—even though it was not directly dependent on the patient's verbal report of his arousal. Apparently, it affected the underlying state in such a way that only the psychopathic component of his sexual drive was altered.

We are convinced that the success reported here is largely dependent on the careful diagnostic evaluations that allowed the identification of a specific physiological system (in this case, heart rate) as central to the psychopathic behavior problem in terms of both its differential responsiveness to stimuli and the disparity between the physiological and verbal indices of arousal. If correspondingly careful diagnostic work indicates comparable physio-

logical substrates to other behavioral problems, a "biosyntonic" approach to therapy may offer a viable treatment approach to other problems.

Brief Reports

Female Criminal Violence and Differential MMPI Characteristics

Patricia B. Sutker, Albert N. Allain, and Scott Geyer
Department of Psychiatry and Behavioral Sciences
Medical University of South Carolina

A cross-validated approach was used to compare Minnesota Multiphasic Personality Inventory (MMPI) scale elevations and profile patterns produced by female murderers and nonviolent offenders in two geographic regions. Murderers from both prison sources produced subdued group mean profiles, whereas nonviolent offenders were characterized by elevations on Scale 4. Discriminant function classification was highly dependent on scores on Scales 4, 5, K, and A and correctly identified 82% of violent and 78% of nonviolent offenders. A principal-components analysis yielded five components or profile types, but only the component defined by high positive loadings for Scale 4 differentiated between the groups.

Representing perhaps the antithesis of traditional womanhood, female aggressivity would seem to hold great interest for investigators. Yet few studies have described psychosocial factors that differentially characterize violent and nonviolent women (Climent, Rollins, Ervin, & Plutchik, 1973; Cole, Fisher, & Cole, 1968). More often, empirical studies of the psychological parameters of violent behavior among men have been undertaken, with the work of Megargee and associates as the most comprehensive example (Megargee, Cook, & Mendelsohn, 1967; Megargee & Hokanson, 1970). Assuming that certain personality or cognitive characteristics may be predictive of female criminal violence, the present study used a cross-validated approach to identify personality dimensions or patterns measured by the Minnesota Multiphasic Personality Inventory (MMPI) that might be related to extreme violent behavior among female felons.

Subjects were women convicted for murder and nonviolent offenses in the Louisiana Correctional Institute for Women (LCIW) and the Women's Correctional Center (WCC) in South Carolina. Selection in both prisons involved the following steps: random identification of roughly one third of the names from prison rolls (150 in LCIW; 180 in WCC), systematic reduction and

replacement of women unable to read sufficiently well to complete the instruments (10%-15% of those initially selected) or unwilling to participate (2%-5%), and posttest exclusion of women convicted for violent crimes less extreme than murder or manslaughter for the violent group and of women convicted for nonviolent offenses with a record of violent crimes for the nonviolent group. Both samples also excluded newly inducted inmates (imprisoned less than 5 months). The final breakdown of LCIW women ($n = 32$) included 12 violent and 20 nonviolent offenders, and of the 30 women selected at WCC, 10 had been convicted of murder or manslaughter and 20 of drug or property offenses. Distribution by race was equal for violent and nonviolent categories in both prison samples, and groups did not differ on personal or history variables including age, education, age at current offense, months served on current offense, total time incarcerated, and intellectual level. Data collection instruments were the Shipley Institute of Living Scale, Raven's Progressive Matrices, the MMPI, and a structured private interview. Sixteen MMPI scales were scored and converted to T -score values: 10 clinical, 3 validity, Welsh's A and R , and Barron's Ego Strength scales. The revised Overcontrolled Hostility (O-H) scale (Megargee et al., 1967) was also scored, but no T -score transformation was applied.

Violent criminal offenders responded to the MMPI in a less deviant fashion than nonviolent felons, and group mean profiles fell completely within the "normal" range. LCIW group comparisons showed significant differences on Scale 4

Requests for reprints and for an extended report of this study should be sent to Patricia B. Sutker, Department of Psychiatry and Behavioral Sciences, Medical University of South Carolina, 171 Ashley Avenue, Charleston, South Carolina 29403.

alone, $F(1, 30) = 4.29$, $p < .05$, and differences for WCC were found on Scales 4, $F(1, 28) = 6.10$, $p < .05$, and 2, $F(1, 28) = 5.29$, $p < .05$. Between-group comparisons for prison groups revealed only one difference—WCC murderers produced more elevated scores on Scale L, $F(1, 20) = 6.76$, $p < .05$, than LCIW murderers. The two prison samples were combined for subsequent analyses. For combined samples, murderers scored lower on Scale F, $F(1, 60) = 4.45$, $p < .05$, and Scale 4, $F(1, 60) = 10.09$, $p < .01$, and higher on Scale K, $F(1, 60) = 6.07$, $p < .05$, and Scale 5, $F(1, 60) = 5.09$, $p < .05$. Comparisons on the O-H scale showed no significant differences between violent and nonviolent groups, $F(1, 60) = .95$, $p > .05$. Prediction of group identity using stepwise discriminant function analysis was highly accurate (82% of violent and 78% of nonviolent offenders were classified), with categorization heavily dependent on scores on Scales 4, 5, K, and A.

Principal-components analysis with varimax rotation identified five independent components with eigenvalues greater than 1.00, which accounted for 78% of the total variance. Components represented anxiety maladjustment, activity, conversion reaction, masculinity-femininity, and social deviance dimensions. Group comparisons of mean factor scores showed that only the factor suggesting social deviance, defined by high positive loadings on Scale 4 and moderate negative loadings on Scale L, was differentially related to offender classification, $F(1, 60) = 9.44$, $p < .01$. Using the Meehl system of profile classification, 50% of the murderer profiles were categorized as normal, as compared to 25% of nonviolent offenders. Within the nonviolent offender group, 42.5% of profiles were classified as conduct disorder, 30% as psychotic, and 2.5% as neurotic, whereas only 14% of murderer profiles were labeled *conduct disorder*; 36%, *psychotic*; and 0%, *neurotic*. The most prevalent code type among murderers was 4-5/5-4 (23%), with 1-6/6-1, 2-8/8-2, and 6-8/8-6 each accounting for 10% of the profiles. In contrast, the 4-5/5-4 type was characteristic of 5% of the nonviolent offenders. There was only one 4-9/9-4 profile among murderers, but this type accounted for 30% of nonviolent offender profiles.

Results suggest that there are significant and reliable relationships between extreme criminal violence and aspects of MMPI performance. Women convicted of criminal homicide tended to respond to MMPI items in a manner reflective of minimal involvement in a socially deviant life-style, with reluctance to admit unusual psy-

chological symptoms, limited personal insight, moderate levels of interpersonal anger, and less identification with culturally defined femininity than nonviolent offenders. Thus, women who murdered could be said to be more defensive, less in touch with impulses to action, more socially conforming, and more removed from a stereotyped definition of femininity.

These data also suggest a negative relationship between membership in a violent offender group and sociopathic psychopathology—a finding compatible with the notion that so-called aggressive psychopaths are found infrequently to be extremely assaultive and rarely to kill (Gibbens, Pond, & Stafford-Clarke, 1959). Findings also describe a personality constellation in agreement with the Megargee et al. (1967) hypothesis that overcontrolled persons may more often commit more violent crimes than those who are undercontrolled, although no differences were observed on the O-H scale developed by Megargee et al. using male samples to measure overcontrolled hostility.

That the masculinity-femininity dimension may be implicated as associated with female criminal violence is interesting, in that homicide is a crime most easily identified with masculine aggressive behaviors. Though Scale 5 may be a poor descriptor of social posture regarded as feminine, masculine, or both, its significance in this study underscores the need for further research focusing on female attitudes toward self, men, and society and the relationship of such attitudes toward assertive behavior. Finally, results point to a striking similarity in MMPI profile configurations across samples, with particular focus on differences on Scale 4, a preponderance of normal profiles among murderers, and concentration of conduct disorder classifications for nonviolent offenders. These findings neither generalize to less deviant populations nor predict violent behavior in general. However, they target areas for future research and suggest the need for studies to identify the various personality or cognitive factors potentially predictive of inappropriately aggressive behavior among women in less deviant groups. Such investigations would also have direct implications for the myriad of female assertiveness training classes springing up across the nation.

Turning On or Turning Off: Sensation Seeking or Tension Reduction as Motivational Determinants of Alcohol Use

Raymond M. Schwarz, Barry R. Burkhart, and Samuel B. Green
Auburn University

To assess the relative influences of sensation-seeking or tension-reduction motives on drinking behavior, 242 college students completed the Sensation Seeking Scale, the S-R Inventory of General Trait Anxiousness, and a self-report index of drinking behavior. Using correlational and multiple regression procedures, the data consistently indicated a strong positive relationship between sensation seeking and alcohol use, whereas the relationship between anxiety and alcohol use was nonsignificant. The importance of sensation-seeking motives to a comprehensive motivational theory of alcohol is discussed.

Physiologically, alcohol functions to depress central nervous system activity. This decrease in cortical arousal as a primary consequence of alcohol consumption has served as a starting point for much of the psychologically oriented theory about drinking behavior, because it has been assumed that the psychological motivation for alcohol use must complement or reflect these physiological effects. The concept of tension reduction seemed to be the best psychological analogue to the decrease in cortical arousal occurring as a function of drinking; that is, drinking leads to decreased cortical arousal, which results in a decrease in tension anxiety.

Recent research addressed to the alleged relationship between anxiety and alcohol use has returned mixed findings. Alcoholic populations generally have higher levels of self-reported anxiety than normals; however, other studies have found no relationship between self-reported anxiety and alcohol use with college students. To further complicate matters, several studies have demonstrated that consumption of alcohol is associated with increased mood disturbances.

In an attempt to explain these discrepant findings, it has been suggested that researchers distinguish between the tension-reducing effects of alcohol and the fact that organisms may or may

not drink alcohol for its tension-reducing effects. It may be that even if alcohol is a pharmacological sedative, people drink for other reasons.

One such reason can be derived from the concept of optimal level of stimulation. Given that alcohol use is not clearly or consistently related to tension-reduction needs, it may be that a comprehensive theory of alcohol use requires attention to stimulus-seeking needs. Studies of premorbid personality characteristics of problem drinkers have shown many of them to be impulsive, restless, and nonconforming; this description bears a marked resemblance to the characteristics of high stimulus seekers. Additionally, some studies have found significant correlations between drinking behavior and measures of stimulus seeking.

The present study was designed to examine the relationship between tension reduction and sensation-seeking needs and alcohol use. If drinking behavior is a consequence of one or both of these motives, then the amount and frequency of alcohol use should be correlated with measures of the motivational predisposition.

The subjects for this study were 242 undergraduates, both male ($n = 130$) and female ($n = 112$). Each student was asked to complete the Sensation Seeking Scale (SSS); the S-R Inventory of General Trait Anxiousness (S-R GTA); and an index of the individual's drinking behavior, which was based on both frequency and amount of alcohol use. The SSS is composed of five interpretable factor scales: Thrill and Adventure Seeking (TAS), Disinhibition (Dis), Experience Seeking (ES), Boredom Susceptibility (BS), and a General scale of sensation seeking.

This article is based on a thesis submitted by the first author and directed by the second author in partial fulfillment of the requirements of the master's degree from Auburn University.

Requests for reprints should be sent to Barry R. Burkhart, Department of Psychology, Auburn University, Auburn, Alabama 36830.

The S-R GTA is a self-report inventory designed to measure anxiety across four general stimulus situations: interpersonal, physical danger, ambiguous, and routine situations.

The zero-order correlations between the SSS and the drinking index are presented in Table 1. Significant positive correlations were obtained between all five scales and the drinking index. The zero-order correlations between the drinking index and anxiety scales were nonsignificant, with the single exception of the correlation between the Physical Danger anxiety scale and the drinking index. However, this relationship was weak ($r = -.15$, $p < .05$) and, more noteworthy, in the negative direction.

To determine the relative contributions of sensation seeking and anxiety-reduction motives to drinking behavior, several multiple regression analyses were computed. The drinking index was predicted significantly by the SSS, $F(5, 236) = 23.68$, $p < .001$; by the S-R GTA, $F(4, 237) = 2.64$, $p < .05$; and by both combined, $F(9, 232) = 13.58$, $p < .001$. In examining the relative contribution of both scales, it was found that when the SSS scores were stepped into the regression equation first, they accounted for 33% of the total variance of the drinking index scores. The anxiety scales contributed only an additional 1% to the total variance accounted for by the SSS scales. When the anxiety scores were entered into the regression analysis first, they accounted for only 4% of the total variance in predicting the drinking index scores. The addition of the SSS raised the variance accounted for to 34%. In both analyses, the Disinhibition scale added more to the total R^2 than the other scales combined.

The results of the present study can be easily summarized. Alcohol use was not correlated positively with the level of self-reported anxiety even when anxiety was considered as a multidimensional construct. On the other hand, alcohol consumption was strongly related to stimulus-seeking needs, particularly needs to engage in disinhibited forms of sensation seeking. These results, in conjunction with other recent findings, do not support a strict tension-reduction hypothesis and suggest that a new analysis of the motivational determinants of alcohol use is in order.

It should be noted that these data are specific to the young adult population represented by our sample. Moreover, studies with older, alcoholic populations often offer support for an association between anxiety and alcohol use. In combination, these results suggest that there may be a partial developmental course in the relation-

Table 1

Correlations Between Sensation Seeking Scales and Drinking Index Scores

Scale	Drinking index

*** $p < .001$.

ship between sensation seeking, anxiety, and alcohol use. For young adults, drinking may serve primarily as an outlet for sensation-seeking needs, whereas, later in life, especially for vulnerable individuals, drinking may come to serve as a coping mechanism for feelings of anxiety and stress.

Among the various dimensions of sensation seeking, the most powerful predictor of drinking behavior was the Disinhibition scale, which is best described as measuring a need for extraverted, hedonistic social involvement. The question that obviously presents itself is, "Why does a pharmacological sedative serve as a releasing mechanism for socially extraverted, sensation-seeking behaviors?"

Our hypothesis is that alcohol disinhibits behavior, because of the well-established cultural expectancy that drinking leads inevitably to an inability to exercise moral or social restraint, not just because of its pharmacological effects. Recent research, which found that alcohol disinhibits behavior only if the subjects were told that they were drinking alcohol, offers some support for this hypothesis. Drinking, in effect, provides a culturally sanctioned "time-out" from social control, during which exhibitionistic, hedonistic behavior may be expressed with impunity. It follows, therefore, that individuals with a strong need to engage in disinhibited behavior will be more likely to turn to drinking because of this culturally established expectancy.

In summary, alcohol may be described as serving as a "releaser" for normally restrained social behaviors. If so, then theories of alcohol use will need to take into account the reinforcement potential provided by access to such disinhibited states, especially in individuals with strong motivational needs for sensation seeking.

Therapist and Client Perceptions of Alternative Roles for the Facilitative Conditions

Robert B. Slaney
University of Akron

The present study examined therapist and client perceptions of one of two transcripts of psychotherapy—one using the facilitative conditions as a treatment and one using them as intermediate variables leading to the suggestion of assertive training. Data were obtained from 100 therapists-in-training and 50 clients. For the therapist group, assertive training was estimated as more effective and the behavioral therapist was seen as more expert and appealing. No differences were found on therapist understanding. For the client group, no significant differences were found. The findings are discussed with their implications for future research.

The presence of the facilitative conditions (Carkhuff, 1969) in current research, writing, and professional and paraprofessional training programs supports Bergin's statement that "their presence and influence is ubiquitous" (Bergin & Suinn, 1975, p. 521). However, while some theorists, such as Carkhuff, seem to place emphasis on the conditions as a primary mode of treatment, others (e.g., Lazarus, 1971) stress the intermediate relationship-enhancing aspects of these variables.

The present study used two groups, therapists and clients, to examine perceptions of the role of the facilitative conditions in psychotherapy. For the therapist group the participants were 50 male and 50 female graduate students in rehabilitation counseling, counseling psychology, and clinical psychology who were involved in training programs in mental health facilities in the Syracuse, New York, area. Data were gathered over a 2-year period. The distribution of students was rehabilitation, 38; counseling, 23; and clinical, 39. All participants had had experience in the treatment of clients. They were randomly assigned to treatment conditions by sex and area of specialization. The mean age was 26.36 years.

Preparation of this article was partially supported by Veterans Administration research Grant 7979-01 while the author was a staff member at the Syracuse Veteran's Administration Hospital.

The author wishes to thank Harvey A. Taub for his helpful comments on an earlier draft of this manuscript.

Requests for reprints and for an extended report of this study should be sent to Robert B. Slaney, Department of Psychology, University of Akron, Akron, Ohio 44325.

The mean educational level was 17.53 years. There were no significant differences based on age or years of education.

A written transcript (Slaney, 1977) represented an excerpt from a therapy session. The transcript consisted of nine client-therapist interactions. The client statements portrayed a male who was having difficulties at work, at home, and in social situations because he was anxious, unsure of himself, and unassertive. The therapist responses were designed to represent facilitative responses using Carkhuff's (1969) Empathy Scale. Two independent raters, experienced in the use of Carkhuff's scale, rated all but one response as meeting or exceeding the criterion of 3.0. A Pearson product-moment correlation of the ratings was .86.

A second transcript was devised, which differed from the first only in the last therapist response. Instead of a facilitative response, the suggestion of assertive training was made. This response was rated below 3.0 on Carkhuff's (1969) scale. A group of seven raters, all experienced therapists with PhDs, were asked to judge the appropriateness of the use of assertive training with this client. A 7-point rating scale ranging from 1 (very inappropriate) to 7 (very appropriate) was used. The mean rating was 5.6.

The transcripts were randomly distributed. After reading them, subjects completed a rating scale, which included an estimate of the effectiveness of the eventual outcome of the treatment and three therapist characteristics: expertness, understanding, and appeal. The scales were 8-point Likert-type scales ranging, for example, from extremely inexpert to extremely expert.

The mean ratings were slightly to moderately positive. None was negative. A 2×2 (Treatment \times Sex) analysis of variance was performed for each of the therapist rating scale items. The results indicate that for perceptions of expertness, there were significant differences as a result of treatment; $F(1, 96) = 5.54, p < .05$, with the assertive training therapist perceived as more expert. There were no significant differences on understanding. For appeal there was a significant treatment effect, $F(1, 96) = 6.07, p < .05$; the assertive training therapist was rated as more appealing. And the estimates of the effectiveness of the treatment yielded a significant treatment effect, $F(1, 96) = 5.68, p < .05$, with the effectiveness of assertive training rated as higher than the facilitative conditions. There were no significant differences as a result of sex or the Treatment \times Sex interaction.

To examine the perceptions of clients, the study contained 61 male clients of the Veterans Administration Hospital who were either outpatients at a mental hygiene clinic or patients who were being discharged from an acute inpatient treatment facility. Diagnoses were primarily personality disorders or mixed neuroses. The criteria for inclusion were a willingness to participate, being under 35 years of age, involvement in individual therapy, being considered ready for discharge, and being judged as free of observable symptoms by the therapist involved and two other staff persons making independent judgments. Five clients declined to participate, and six were rated by one or more of the judges as not being free of observable symptoms. The final sample, gathered over an 18-month period, was composed of 50 clients. The mean age was 28.6 years, with a range of 20-35; and the mean educational level was 12.93 years, with a range of 10-18 years. There were no significant differences between the groups on the basis of age or educational level. The transcripts and procedures were the same as for the therapists.

The mean ratings were slightly to moderately positive. A one-way analysis of variance revealed no significant treatment differences on any of the rating scale items.

Overall, the results for the therapist group indicate a preference for the treatment that combined the facilitative conditions with the suggestion of assertive training. The lack of significant differences on understanding would appear to be the result of the higher ratings that the therapists in the facilitative conditions treatment gave to this variable relative to the others.

The lack of significant differences in the rat-

ings of the client group can be seen as countering the expectation that this group would be likely to prefer the suggestion of a specific treatment in a manner analogous to the stereotypical physician-patient interaction. It may be that the client group, having experienced therapy, had a greater appreciation of the facilitative responses. A related possibility is that clients in therapy may have been taught to not expect specific suggestions from their therapists.

An alternative explanation may be that the client group simply lacked the background in experience and theory that the therapist group had and used in rating the transcripts. Similarly, it may be that the particular efforts made to provide valid facilitative responses and an appropriate treatment had a greater effect on the therapists than on the clients. In any event it seems reasonable that the expectations of clients about appropriate treatments were less clear than those of therapists. That the client group rated both treatments positively can be seen as an indication of an overall receptiveness to psychotherapy.

The previous study that used the same transcripts (Slaney, 1977) contained students in introductory psychology courses. The results for this group were similar to the therapist results. Although the reasons for this similarity are not clear, the differences between the student group and the client group raise questions about extending results of studies containing college students to clients, particularly clients in inpatient or outpatient treatment settings.

The lack of women clients is, of course, an important limitation of this study. Another important qualification is that the transcripts presented only one particular client and two possible approaches to treatment. How or whether the perceptions of treatment for counselors and clients vary as a function of the problem that is presented or the treatment suggested is a question that will require further research.

Positive Versus Negative Self-Monitoring in the Self-Control of Smoking

David A. Kantorowitz, Joyce Walters, and Kathy Pezdek
California State College, San Bernardino

This experiment compared smoking treatment programs using negative (recording number of cigarettes smoked) versus positive (recording number of urges resisted) self-monitoring. Subjects participated in one of two similar broad-spectrum treatment programs, within which they either used positive or negative self-monitoring. Over treatment, subjects in both self-monitoring groups demonstrated similarly significant reductions in smoking frequency as compared with a no-treatment control group. These findings were generally maintained at follow-up. Clinical findings call into question the accuracy of the "positive" and "negative" labels used to designate the two self-monitoring modes.

Clinical programs for smoking reduction are generally assessed by subject self-monitoring (Thoresen & Mahoney, 1974). Although several points prior to, during, and after the act of smoking would appear monitorable, clinical researchers have generally asked subjects to record their (a) successfully resisted urges to smoke (positive self-monitoring) or (b) number of cigarettes smoked (negative self-monitoring) (McFall & Hammen, 1971).

Thoresen and Mahoney (1974) have suggested that monitoring resisted urges may prove to be more facilitative to smoking reduction than monitoring the number of smoked cigarettes. Presumably, the act of self-monitoring successfully resisted urges becomes secondarily reinforcing and transforms the urges into SDs for self-control. By focusing on number of cigarettes smoked, SDs for self-punishment may be created, but since these cues appear after the behavior to be controlled, they may be less helpful in controlling the preceding smoking behavior.

Previous research has attempted to assess the effects of self-monitoring free of confounding treatment techniques. McFall (1970) reported that negative monitoring of "unmotivated" students increased cigarette consumption over a 13-day period, whereas positive monitoring decreased consumption. Working with "motivated" students,

however, McFall and Hammen (1971) found similarly significant decreases in smoking among positive and negative monitoring groups. In addition, positive and negative monitoring led to significant changes in study time (Johnson & White, 1971) and in nail-biting (McNamara, 1972), with no significant differences in frequency of smoking between the two modes.

A methodological problem with the aforementioned studies is the confounding of self-monitoring methods with subsequent, uncontrolled usage by motivated subjects of self-evaluation and covert self-praise or punishment (Thoresen & Mahoney, 1974). Additionally, there exists no research comparing different monitoring methods as the assessment vehicle for clinically relevant broad-spectrum self-control programs. This would appear to be an important area in view of the transitory nature of treatment effects produced by self-monitoring alone (Kazdin, 1974). The present study was thus designed to compare positive versus negative self-monitoring as each interacted with similar broad-spectrum behavioral self-control programs for the reduction of cigarette smoking.

Nine volunteer subjects (M age = 36.7) were assigned to self-control with positive monitoring, self-control with negative monitoring, and waiting list control groups. Treatment subjects were randomly assigned to either the positive or negative monitoring groups; subjects who could not attend either of the treatment groups due to scheduling restraints were assigned to the control group. The baseline smoking rates of the positive monitoring, negative monitoring, and control groups were 19.7, 26.8, and 15.6, respectively.

This study is based on a master's thesis completed by the second author, submitted to California State College, San Bernardino.

Requests for reprints should be sent to David A. Kantorowitz, Department of Psychology, California State College, San Bernardino, California 92407.

Both self-control treatments consisted of eight 90-minute group meetings distributed twice a week over 4 weeks. To insure that both experimental groups were taught similar techniques of self-control, each of the treatment sessions was prearranged and standardized. Both groups were instructed to (a) identify, avoid, or isolate cues for smoking, (b) make use of incompatible responses when feeling urges to smoke (such as relaxing, chewing, sucking cloves, etc.), (c) use self-talk and imagery as vehicles for self-reward and punishment, and (d) write contingency contracts for themselves and with others. Subjects in both groups were instructed to reduce their cigarette consumption at their own rate but to attempt to reach abstinence by the eighth session.

Subjects in the negative self-monitoring group were instructed to advance their counters each time they yielded to an urge and decided to smoke. Subjects in the positive self-monitoring group advanced their counters each time they resisted an urge to smoke. Both groups transcribed their daily totals onto written charts, which they brought to treatment sessions.

The control group decreased over treatment by a mean of 1.1 cigarettes a day; one subject reached abstinence. The positive and negative monitoring groups decreased by 14.7 (74.6% of baseline) and 16.8 (62.8%) cigarettes a day, respectively. The number of subjects reaching abstinence were four (positive monitoring) and two (negative monitoring). The follow-up rates of the negative and positive monitoring groups remained, respectively, 16.0 and 10.1 below the baseline of each group; three positive and three negative monitoring subjects remained abstinent.

Because the variance among groups on the pretreatment baseline measure was nonhomogeneous, $F_{\max}(3, 17) = 7.28$, $p < .05$, Tukey's *a posteriori* comparisons among means were made on each of the three treatment groups separately. There was no change in smoking frequency over time for the control group. The negative monitoring group, however, significantly reduced its smoking frequency from baseline to end of treatment ($q = 6.48$, $p < .01$) and from baseline to follow-up ($q = 6.17$, $p < .01$). The positive monitoring group significantly reduced its smoking frequency from baseline to end of treatment ($q = 5.68$, $p < .01$); its smoking frequency was suggestively, but not significantly, different from baseline to follow-up ($q = 3.89$). The nonsignificant finding was due to the highly deviant smoking rate ($z = 5.62$) of one subject. The remaining eight subjects in the positive monitoring group

maintained a significant reduction in smoking at follow-up ($q = 5.35$, $p < .05$).

t tests were performed on the relative differences between baseline and end of treatment, and baseline and follow-up, for the positive versus the negative self-monitoring groups. Contrary to prediction, no significant difference was found between the positive monitoring group and the negative monitoring group at end of treatment or at follow-up. A chi-square analysis of the number of subjects in each group who reached smoking abstinence indicated no difference between positive and negative monitoring at end of treatment or at follow-up. There was a significant difference, however, between the combined self-control groups as compared with the control group at end of treatment and at follow-up, $\chi^2(1) = 5.39$, $p < .025$, at both times.

Since both monitoring groups were paired with broad-spectrum self-control programs, it is not possible to conclude that the results support a facilitative effect of self-monitoring alone. The data do indicate, however, that contrary to the speculations of Thoresen and Mahoney (1974), there was no significant difference in outcome between positive and negative self-monitoring when used as the assessment vehicle for a broad-spectrum self-control program.

Interestingly, only one subject in the negative self-monitoring group reported that the self-monitoring treatment was "negative" or self-punishing on a follow-up questionnaire. Most subjects tended to view negative monitoring in the overall context of their treatment goals, frequently citing the self-reinforcing aspects of watching unresisted urges decline. Unexpectedly, five of eight positive monitoring subjects who completed the follow-up questionnaire indicated dislike of and frustration with this method even though their frequency of resisted urges did increase. Generally cited reasons included "preferring to see cigarette consumption decline" or "lacking feelings of accomplishment." Rather than stressing self-reinforcing effects pursuant to resisting urges, positive monitoring subjects stressed heightened frustration due to increased awareness of resisted urges to smoke. These results suggest that "positively" and "negatively" designated self-monitoring modes may be misnomers. Self-presentation of praise or punishment may solely be a function of the desirability of the self-monitored feedback that is received and independent of the method by which this feedback is procured.

Additional research would be required to investigate whether these speculations match sub-

jects' subjective appraisal patterns subsequent to positively or negatively monitoring clinical progress or reversals

Aspects of the Self-Concept Related to Level of Self-Esteem

Kenneth W. Christian
University of California at Davis

Aspects of the phenomenal self-concept of 30 male subjects varying in self-esteem, using a numerical self-report approach, were studied. Numerical ratings of *importance* and *salience* of self-enumerated positive and negative characteristics were used to generate a series of scores. Significant differences ($p < .005$) were found on an overall self-esteem score, which correlated .59 ($p < .001$) with an independent measure. No significant differences were found on ratings of positive characteristics. Striking differences were noted for negative characteristics. Results suggest that it is how individuals experience negative rather than positive characteristics that plays a determining role in self-esteem.

Difficulties involved in directly assessing the phenomenal self-concept (Wyllie, 1974) have caused recent attention on indirect assessment devices and alternative conceptualizations of self-esteem (e.g. Coopersmith, 1967; Gergen, 1971; Hagey, Smith, & Long, 1969). However, sparse data regarding regularities in the experienced self-concept would amplify our understanding of self-esteem, the present study attempts to examine aspects of the phenomenal self-concept of subjects varying in self-esteem by using a numerical self-report (NSR) approach.

The NSR approach (Christian, 1973) involves attaching subjective meanings to the two extremes of a 100-point scale and requiring subjects to respond numerically regarding this dimension of experience. In the present study, 30 male volunteers, 10 from each of three self-esteem levels (i.e., high, medium, and low) on Coopersmith's Self-Esteem Inventory (SEI), were randomly assigned to interview times with a male interviewer. After an introductory period, the subject was asked to enumerate his positive characteristics. NSRs of the *importance* of each characteristic and ratings for the *salience* (relative presence) of each were requested. Negative characteristics were then elicited, and the same rating process was repeated.

Group differences on an overall self-esteem score generated from the various NSRs were sig-

nificant at the .005 level, $F(2, 27) = 7.898$, and means were in the predicted direction. Furthermore, subjects' scores on overall self-esteem correlated .59 ($p < .001$) with scores on the SEI. These results appear to indicate that as predicted, NSRs concerning various aspects of the self-concept can be combined and transformed into an overall score that discriminates between subjects with different self-esteem levels.

Even though none of the analyses of the various subscores for positive aspects of the self were significant, significant differences were found on the negative self-regard score, $F(2, 27) = 10.244$, $p < .001$, on saliency ratings for negative characteristics, $F(2, 27) = 6.652$, $p < .01$, and on the number of negative characteristics mentioned, $F(2, 27) = 3.806$, $p < .05$.

The high-self-esteem subjects' low negative ratings seem to indicate that they do not experience their negative characteristics in the same way that others do, and that the important difference between individuals differing in self-esteem is the amount of negative, rather than positive, self-regard that they experience.

The pattern of results for the medium group is noteworthy, since they frequently scored highest on both negative and positive measures. These findings may indicate ambivalence and/or uncertainty.

Changes in Preferences for Male and Female Counselors

Elaine F. Walker and Jayne E. Stake

University of Missouri—St. Louis

Past studies have indicated a preference for male therapists among both client and nonclient samples. To test for possible changes in preferences since the time of these studies, 53 male and 76 female applicants for counseling and 140 male and 150 female nonclient undergraduates completed a university counseling service application form that included a question regarding preference for sex of therapist. Although more clients than nonclients expressed preferences, results from both groups indicated a decrease in male counselor preferences.

Past studies of preferences for counselors have indicated that more subjects preferred a male therapist than a female therapist. This finding has been found for both male and female clients (Boulware & Holmes, 1970; Fuller, 1964) and male and female nonclients (Fuller, 1964). One exception to this rule has been the tendency of female nonclient subjects to indicate a preference for a female counselor for some counseling problems (Fuller, 1964).

Boulware and Holmes (1970) reported that their subjects expected male therapists to be more empathic, more knowledgeable, more experienced, and better adjusted; and, presumably, these expectations were the basis for male preferences. However, recent sex role research suggests that previously held notions about the superior competence of male professionals are disappearing (Chobot, Goldberg, Abramson, & Abramson, 1974; Levenson, Burford, Bonno, & Davis, 1975). If this is the case, then a decrease in preferences for male counselors may be expected. The purpose of this study was to explore possible changes in client and nonclient preferences for male and female counselors.

The subjects were 290 undergraduates enrolled in introductory social science courses (140 males and 150 females) and 129 applicants to a university counseling service (53 males and 76 females). Subjects were predominantly from a white, middle-class urban-suburban background. Clients were asked to state their counselor preferences as a part of their applications to a counseling service. As in Fuller's study (Fuller, 1964), subjects could indicate a male preference,

a female preference, or no preference. Nonclient subjects were tested in groups of 15-35 by either a male or female experimenter. They were asked to fill out portions of the application form completed by the clients as though they were applying for counseling.

The percentages of client and nonclient subjects preferring a male or female therapist and the percentages having no preferences are presented in Table 1.

Two questions regarding these sex preferences were considered. First, were subjects more likely to have a preference or not? Second, of those subjects who did state a preference, were they more likely to state a preference for a male or for a female counselor?

The number of male nonclients stating a preference was significantly smaller than the number stating no preference, $\chi^2(1) = 28.35, p < .001$; the number stating a preference for a male counselor was significantly smaller than the number stating a female preference, $\chi^2(1) = 7.61, p < .01$. In the case of female nonclients, the number stating a preference was significantly smaller than the number stating no preference, $\chi^2(1) = 21.66, p < .001$; among those who did state a preference, an approximately equal number preferred each sex. In summary, over 70% of the nonclients gave no preference, and a preference for a male counselor was given by only 12% of the total group.

To determine if the presence of female experimenters in this study accounted for differences between the results of this and earlier studies (which included male experimenters only), the relationship between sex of experimenter and preference (male, female, or none) was tested by a chi-square test of independence. This relationship was not significant; hence, the

Requests for reprints should be sent to Jayne E. Stake, Department of Psychology, University of Missouri, St. Louis, Missouri 63121.

Table 1
*Percentages of Nonclients and Clients
 Expressing Preferences for Counselors*

Subjects	Counselor preference			n
	Male	Female	None	
Nonclient				
Male	7.14	20.00	72.86	140
Female	16.00	14.67	69.33	150
Client				
Male	18.87	16.98	64.15	53
Female	3.95	46.05	50.00	76

decrease in preference for males cannot be explained by the presence of female experimenters.

Although male clients tended not to give a preference, the difference in number giving and not giving a preference was not significant; among males with a preference, an approximately equal number stated a preference for each sex. Among female clients, half stated a preference, and more of these subjects preferred a female counselor, $\chi^2(1) = 25.29$, $p < .001$. These findings also indicate a decrease in preference for males; in the total client sample, only 10% preferred a male counselor.

Differences in the preferences of client and nonclient groups were tested in 2×2 chi-square analyses. The client group was more likely to state a sex preference than was the nonclient group, $\chi^2(1) = 29.26$, $p < .001$; among those stating a preference, clients were more likely than nonclients to state a preference for a same-sex counselor, $\chi^2(1) = 21.89$, $p < .001$. Hence, the client group did tend to express more concern for the sex of their counselors than did the nonclient group.

These differences between the client and nonclient samples may reflect the different circumstances under which preferences were given, or

they may reflect a difference in the type of undergraduates included in the client and nonclient groups.

Although the preferences of the nonclient sample do not coincide closely with the preferences of the perspective clients, the nonclients in the present study can be compared to nonclients in earlier studies (Boulware & Holmes, 1970; Fuller, 1964). Fewer nonclients in the present study indicated a preference for male counselors. This finding suggests that most present-day undergraduates do not view male counselors as superior to female counselors.

The client group is more clearly representative of applicants for counseling. On the basis of the client sample, it appears that a substantial proportion of prospective clients do have preferences; however, in contrast to earlier findings, most of the female clients who indicated a preference wished to see a female counselor, and almost half of the male clients also preferred a female counselor. This change suggests that female counselors are now being viewed more positively by applicants for counseling.

Imaging Vividness and the Outcome of in Vivo and Imagined Scene Desensitization

John M. Dyckman and Philip A. Cowan
University of California, Berkeley

This study reexamined the role of imaging vividness in desensitization success. Scores on the Betts Questionnaire on Mental Imagery were used to divide 48 snake-phobic subjects into high, medium, and low vivid groups, who were assigned to imagined scene or in vivo desensitization treatments. Imaging vividness was assessed at scheduled points during therapy. Significant decreases in behavioral and self-reported fear were observed after both treatments, though in vivo desensitization produced significantly greater fear reduction. Intherapy imaging vividness scores were significantly correlated with therapeutic success and were superior to pretherapy ratings as predictors of outcome.

Imagination of fear-relevant scenes is central to most systematic desensitization procedures. However, previous investigators have failed to find a positive relation between imaging vividness and desensitization success. To examine this apparent paradox, we refined the method of previous studies and conducted the following experiment.

Forty-eight snake phobics were pretested to establish initial fear level. A behavioral avoidance test, self-ratings of fear during this test, a questionnaire on attitudes toward snakes were used to assess fear of snakes, and the Fear Survey Schedule (Wolpe & Lang, 1964) was used to measure general fearfulness. Subjects were then separated into high, medium, and low imaging ability groups on the basis of scores on the Betts Questionnaire on imagery vividness, and were assigned to one of two standardized, individually administered desensitization procedures: imagined scene (conventional) or in vivo desensitization. Subjects in in vivo treatment were asked to enact, rather than imagine, each hierarchy scene. Imaging vividness during therapy was assessed by subject self-ratings at 19 scheduled points. Posttesting was scheduled between 1 and 3 days after completion of the treatment, and the behavioral and self-report measures were repeated.

Analyses of variance of Treatment \times Pretherapy Imaging Vividness Condition indicated no

significant differences among the groups on initial fear levels. Repeated measures analyses of variance revealed that mean posttherapy levels of fear were significantly lower than at pretesting on all measures. Snake phobics did not show significant improvement on repeated testing alone (McLemore, 1972), so the observed changes may be attributed to the treatment.

Analyses of covariance with pretherapy levels of the dependent measures as covariates showed that in vivo therapy produced significantly greater mean fear reduction than imagined scene desensitization on all measures except the Fear Survey Schedule. In vivo treatment was also a more stressful experience for the subjects, who required on the average more scene presentations to complete the hierarchy (for in vivo, $M = 81.1$, for imagined scene, $M = 79.4$) $t(46) = 2.24$, $p < .05$.

In imagined scene desensitization pretherapy, imaging vividness scores correlated $-.41$ ($p < .05$) with posttherapy avoidance of a live snake but nonsignificantly with all other measures. Imaging vividness measured during therapy, however, was highly associated with improvement, correlating with posttherapy levels of the dependent variables as follows: $-.70$ ($p < .001$) with behavioral avoidance of a live snake, $-.60$ ($p < .01$) with self-rated fear during the behavioral test, $-.49$ ($p < .05$) with attitudes toward snakes, and $-.02$ (ns) with the Fear Survey Schedule.

These results suggest several conclusions. Pretherapy imagery inventories like the Betts are currently of limited utility in predicting desensitization success, but imaging performance is

Requests for reprints and for an extended report of this study should be sent to John M. Dyckman, who is now at the Psychiatry Clinic, Kaiser Medical Center, 975 Sereno Drive, Vallejo, California 94590.

important. Betts scores are useful in screening out very low vivid imagers (in our sample, those who scored above 102.5). These patients can benefit greatly from the extra time and expense required to arrange in vivo treatment. The Betts, or any pretherapy imaging measure, should include items taken directly from the proposed hierarchy to assess the subject's ability to clearly imagine stressful material. Imaging ability is clearly related to the outcome of imagined scene desensitization. The failure of previous studies to disclose this relation may stem from a failure to assess imaging activity during

treatment, and it reminds us that psychotherapy research must combine examination of process with evaluation of outcome to produce meaningful results.

Psychophysiology of Fear Imagery: Differences Between Focal Phobia and Social Performance Anxiety

Theodore C. Weerts and Peter J. Lang
University of Wisconsin

Spider phobics and speech anxious subjects imaged fear scenes with spider and public-speaking content and a series of standard scenes that were constructed to vary in degree of emotional arousal and movement. Heart rate, skin conductance, and ocular activity were recorded. Spider phobics rated all imagery contents as more vivid and reported more scene movement than speech anxious subjects. Both groups responded to their own fear scenes with higher ratings of emotion and a greater physiological response than to the other group's fear scenes. The arousal response of spider phobics to relevant fear scenes was greater than that of speech anxious subjects. The data suggest that the outcome of imagery-based therapies may be partly determined by type of fear.

The present research reexamined the finding (Lang, Melamed, & Hart, 1970) that small animal phobics and subjects with anxiety over public speaking differ in the vividness and intensity of their emotional imagery. Specifically, it was designed to determine if focal phobics give higher vividness and emotional arousal ratings than subjects with performance anxiety, are more responsive physiologically irrespective of scene content, or whether they show this greater response only to emotionally activating or focal fear materials. It was also designed to examine projected visual movement in fear imagery, as rapidity of stimulus change is associated with the genesis and evocation of small animal fears and to consider trait anxiety and general physiological reactivity as factors prompting imagery differences between fear groups.

Method

Two groups of undergraduate subjects were studied: 9 females and 2 males with a maximum spider item response on the Fear Survey Schedule (FSS), and with Spider questionnaire scores at the 75th percentile or above (all of these subjects professed no speech anxiety on the FSS and were below the Speech Anxiety Questionnaire

median); 13 females and 3 males fearful of public speaking on the FSS and from the top 25% of students in public-speaking fear (reporting no spider fear (FSS) and below the median on the Spider Fear Questionnaire (Klorman, Weerts, Hastings, Melamed, & Lang, 1974)).

All subjects visualized eight standard scenes, two from each of four content categories: scenes (a) high in emotional arousal and high in movement (e.g., panic in a burning movie theater); (b) high in movement and low in arousal; (c) low in movement and high in arousal; and (d) low in both movement and arousal (e.g., sitting at a table in the library). All subjects were also administered four fear scenes, two relevant to spider phobia (e.g., a spider crawling up your sleeve) and two related to performance anxiety (e.g., presenting a report in class).

The scenes were presented as text on a computer oscilloscope display with a 30-sec eyes-closed period for visualization. After each scene subjects reported emotional arousal during the image, perceived movement, and image vividness.

During all scenes, horizontal and vertical eye movements, skin conductance, and heart rate (HR) were continuously monitored. In addition, spontaneous skin conductance activity and habituation to a 100-dB (A) tone were assessed.

Results

The two fear groups did not differ in Taylor Manifest Anxiety Scale (TMAS) scores, in spontaneous skin conductance activity, or in skin conductance response (SCR) habituation to pure tones.

This research was supported in part by National Institute of Mental Health Grant 10993. Requests for reprints and an extended report of this study should be sent to Peter J. Lang, Department of Psychology, University of Wisconsin, Madison, Wisconsin 53706.

Standard Scene Ratings

There was no significant group difference in report of emotional arousal to the standard scenes ($F < 1$). However, spider phobics gave significantly higher vividness ratings than did speech anxious subjects to all scenes, $F(1, 25) = 7.47$, $p < .02$. Spider phobics also tended to see more movement in the standard scenes than subjects with performance anxiety, $F(1, 25) = 3.63$, $p < .10$.

All subjects found the low-arousal scenes to be less emotionally stimulating, $F(1, 25) = 99.36$, $p < .001$, and marginally more vivid than the high-arousal scenes, $F(1, 25) = 4.14$, $p < .06$. The highest vividness ratings were generated by high-movement scenes when the arousal properties of the scene were low. High movement in combination with high arousal produced the lowest vividness ratings, $F(1, 25) = 7.00$, $p < .03$. The latter findings are consonant with Lang's (1977) view that multiple response propositions increase the information-processing load in imagery and could thus attenuate reported vividness.

High-TMAS subjects regardless of their specific fear tended to give similar vividness ratings to all scenes; low-anxious subjects showed a specific reduction in vividness reports to high-arousal scenes, $F(1, 32) = 6.07$, $p < .025$. This finding suggests that the lower mean vividness ratings found for arousing stimuli than for neutral stimuli in the total sample may be due to the low-anxiety subjects, who are less likely to spontaneously image arousal contents and are thus less practiced in this task.

Physiological Response to Standard Scenes

No simple differences between fear groups in response to the standard scenes were observed for any physiological measure. However, for the spider phobics high arousal was associated with an increase in eye movement, whereas for the speech anxious, low-arousal scenes generated more eye movement, $F(1, 23) = 5.56$, $p < .05$ (vertical movement). Also, speech anxious subjects, unlike spider phobics, increased HR during high-movement scenes, $F(1, 22) = 6.71$, $p < .03$. Although these findings imply some physiological difference between fear groups, the interactions were not predicted, and cross-validation should precede further interpretation.

Fear Scene Ratings

The four fear scenes were administered randomly among the standard scenes but were subjected to a separate statistical analysis. The spider phobics rated fear scenes as more vivid than did public-speaking anxious subjects, $F(1, 25) = 13.74$, $p < .05$. The spider phobics also rated spider scenes as significantly more vivid than the public-speaking scenes; the two fear scene types did not differ in vividness for the speech anxious, and both their ratings were similar in level to the ratings assigned by spider phobics to speech anxiety scenes, $F(1, 25) = 5.54$, $p < .05$.

Spider phobics tended to rate both fear-relevant and fear-irrelevant scenes as more arousing than did speech anxious subjects, $F(1, 25) = 12.53$, $p < .005$. However, rating differences between the two scene types were about equal for the two fear groups, and both groups assigned emotional arousal ratings to their fear-irrelevant scenes similar to that given to their standard low-arousal scenes.

Spider phobics found significantly more movement in their fear-relevant scenes than they did in the speech scenes, and they found more in these spider scenes than the speech anxious reported experiencing in either scene type, $F(1, 25) = 15.67$, $p < .001$.

Physiological Response to Fear Scenes

Eye movements did not vary significantly with either scene type or phobic group. However, both groups tended to produce faster HR, $F(1, 23) = 7.34$, $p < .03$, and a greater total SCR, $F(1, 25) = 7.40$, $p < .025$, to their fear-relevant scenes than to fear-irrelevant scenes. Furthermore, the spider phobics had higher mean responses in their relevant fear imagery (HR = 78.3 beats/min, SCR = $.015 \mu\Omega^{-1}$) than the speech anxious in their relevant scenes (HR = 74.5 beats/min, SCR = $.008 \mu\Omega^{-1}$).

Discussion

In summary, the data support the hypothesis that small animal phobics generate more vivid imagery than subjects with social performance anxiety. The fear-relevant images of spider phobics are not only more vivid, but they also prompt somewhat stronger physiological response and higher ratings of affect. The results

are also consistent with the notion that object movement may play a role in small animal fears. These differences between fear groups were unrelated to differences in anxiety or general patterns of physiological reactivity. They are consistent with the hypothesis that focal phobics' imagery, experiences of fear situations, and perhaps their potential therapeutic responses, are significantly different from those of socially anxious subjects. These results prompt us to re-evaluate research on imagery therapy that was based on only one of these populations.

Correlations and Factor Analysis of the WISC-R and the Peabody Picture Vocabulary Test for an Adolescent Psychiatric Sample

Alan Dellhorn

Department of Psychiatry
Hennepin County Hospital, Detroit, Michigan

Valerie Klinge

Lafayette Clinic, Detroit, Michigan

Wechsler Intelligence Scale for Children Revised (WISC-R) and Peabody Picture Vocabulary Test (PPVT) scores of adolescent psychiatric patients were correlated and factor analyzed. The purposes were to explore the factor structure of these scores among a psychiatric sample, the comparability with other samples in the literature and to determine whether the PPVT adds *independent* information to an intellectual assessment. Three factors emerged that were similar to previously reported factors among other adolescent samples. The PPVT loaded heavily on the factors emerging from the WISC-R, suggesting that the PPVT adds little to information gained from the WISC-R.

The purposes of this study were to explore the factor structure of the Wechsler Intelligence Scale for Children Revised (WISC-R) with an adolescent psychiatric sample and to compare the factor structure of this sample with those previously reported. Kaufman (1971) and Kaufman & Kaufman (1975) reported that the WISC-R and PPVT scores among the adolescent psychiatric sample were similar to those reported for the general adolescent population. The WISC-R and PPVT scores were correlated and factor analyzed. The results of the factor analysis of the WISC-R and PPVT scores were compared with the results of the factor analysis of the WISC-R and PPVT scores reported by Kaufman & Kaufman (1975).

The WISC-R and PPVT scores were correlated and factor analyzed. The results of the factor analysis of the WISC-R and PPVT scores were compared with the results of the factor analysis of the WISC-R and PPVT scores reported by Kaufman & Kaufman (1975). The results of the factor analysis of the WISC-R and PPVT scores were compared with the results of the factor analysis of the WISC-R and PPVT scores reported by Kaufman & Kaufman (1975).

The results of the factor analysis of the WISC-R and PPVT scores were compared with the results of the factor analysis of the WISC-R and PPVT scores reported by Kaufman & Kaufman (1975).

The results of the factor analysis of the WISC-R and PPVT scores were compared with the results of the factor analysis of the WISC-R and PPVT scores reported by Kaufman & Kaufman (1975).

95.01 (SD 18.00). The difference between these two scores was significant using a *t* test for unpaired means (1999): $t = 3.70, p < .001$.

A correlational matrix was computed for the WISC-R IQ scores and subtests and the PPVT IQ. The intercorrelations among the WISC-R subtest scores were all significant ($p < .05$), except that Digit Span was not significantly related to Picture Completion ($r = .10, p > .05$) or to Picture Arrangement ($r = .15, p > .05$). The significant correlation coefficients of the WISC-R subtest scores ranged from .19 to .79. The correlation coefficients of the WISC-R scores with the PPVT-B IQ ranged from .21 to .79 and were all significant ($p < .05$, at least), including those for WISC-R Full Scale IQ ($r = .78, p < .001$), the WISC-R Verbal IQ ($r = .79, p < .001$), and the WISC-R Performance IQ ($r = .65, p < .001$).

From a principal components factor analysis using a three-factor varimax rotation (three factors emerged that accounted for 93.8% of the total variance, Table 1 presents the complete pattern of loadings on the three factors and identifies those variables that exceeded the loading criterion of .4). Factor 1, Verbal Comprehension, accounted for 38.7% of the variance in a stepwise determination. Factor 2, Perceptual Organization, accounted for an additional 8.7% of the variance. Factor 3, Comprehension and Attention, accounted for another 6.5% of the variance. As can be seen, the PPVT-B IQ was above the loading criterion on both Factors 1

Table 1
Loadings of the WISC-R Scores and PPVT IQ

Test	Factor		
	1	2	3
Information	.824	.290	.142
Similarities	.750	.447	.216
Arithmetic	.444	.395	.489
Vocabulary	.822	.310	.174
Comprehension	.649	.375	.449
Digit Span	.234	.095	.370
Picture Completion	.305	.683	-.007
Picture Arrangement	.375	.577	.122
Block Design	.368	.708	.234
Object Assembly	.197	.760	.128
Coding	.272	.302	.572
PPVT IQ	.748	.443	.048

Note. WISC-R = Wechsler Intelligence Scale for Children-Revised; PPVT = Peabody Picture Vocabulary Test. The loading criterion was .40.

The factors that emerged are very similar to those reported from other samples (Kaufman, 1975; Van Hagen & Kaufman, 1975). The first and second factors, Verbal Comprehension and Perceptual Organization, appear consistently in such studies and offer construct validity to the separation of Verbal and Performance scores on the WISC-R. The third factor, including Arithmetic and Coding, is very similar to the Freedom from Distractibility factor described elsewhere (Kaufman, 1975), which also includes Digit Span. These findings suggest that the WISC-R scores of an adolescent psychiatric

sample can be compared meaningfully to those of retarded or normal children, since there seem to be no qualitative differences in the structure of the intellectual abilities tested among the three groups.

The substantial loadings of the PPVT-B IQ on the two main factors in this study suggest that the PPVT adds little to the knowledge gained from the WISC-R. Although the correlation between the PPVT-B IQ and the WISC-R Full Scale IQ is rather high, studies using other than correlational designs indicated that the PPVT IQ should not be used as an estimate of the WISC-R IQ (see, e.g., Condit et al., 1976).

Suicide and Transparency Responses on the Rorschach: A Replication

Jill Rierdan
Wellesley College

Elizabeth Lang and Sara Eddy
Human Resource Institute, Boston, Massachusetts

In 1974 Blatt and Ritzler reported that the presence of transparency and cross-sectional responses on the Rorschach differentiated individuals who completed suicide from non-suicidal individuals. This study attempted to cross validate those findings by comparing the Rorschach protocols of 14 individuals who committed suicide with those of a matched sample of individuals who had not committed suicide. In keeping with Blatt and Ritzler's results, the group of suicidal individuals gave a greater number of transparency and cross-sectional responses than did the group of non-suicidal individuals thus indicating the utility of the Rorschach in predicting suicide.

In a review of studies attempting to assess the predictive validity of the Rorschach for identifying suicidal individuals Neuringer in 1965, concluded his attempt to predict suicide using different methods of reading the Rorschach have produced equivocal results. He concluded such results are methodological confusions. In a more recent, however, Neuringer not only criticized earlier work claiming an methodological validity for the Rorschach, but also suggested that the Rorschach might emerge in the future as a predictor of suicide.

Although the validity of the Rorschach as a suicide predictor has not been demonstrated, the Rorschach is a construct that characterizes individuals in the same way. However, a firm conclusion regarding its validity is premature. The Rorschach is a projective test that has been used in a number of ways and in different settings. It is a measure of personality and of psychological relationships. It is a measure of the individual's perception of the world and of the world's perception of the individual. It is a measure of the individual's perception of the world and of the world's perception of the individual. It is a measure of the individual's perception of the world and of the world's perception of the individual.

The present study of Blatt and Ritzler (1974) was a replication of their study. They compared the Rorschach protocols of 14 individuals who committed suicide with those of a matched sample of individuals who had not committed suicide. In keeping with Blatt and Ritzler's results, the group of suicidal individuals gave a greater number of transparency and cross-sectional responses than did the group of non-suicidal individuals thus indicating the utility of the Rorschach in predicting suicide.

Correspondence should be sent to Jill Rierdan, Wellesley College, Wellesley, MA 01981.

that the former group gave a significantly greater number of transparency and translucency responses on the Rorschach than did the latter. In concluding the discussion of their investigation, Blatt and Ritzler acknowledged the need for cross-validation. The present investigation provides this needed replication.

The Rorschach protocols of 14 patients who had committed suicide after their hospitalization in a short-term intensive care facility were examined. The sample of 14 suicides contained 4 females and 10 males ranging in age from 19 to 44 ($M = 27.5$), in Wechsler Adult Intelligence Scale (WAIS IQ) from 82 to 127 ($M = 107.2$), and in number of Rorschach responses from 10 to 67 ($M = 26.0$).

From the records of patients hospitalized at the same facility, 14 controls were selected using a matched-pairs technique such that the control sample contained 4 women and 10 men, whose ages ranged from 17 to 46 ($M = 29.0$), whose WAIS IQ ranged from 86 to 123 ($M = 107.2$), and whose number of Rorschach responses ranged from 11 to 62 ($M = 25.9$). t tests for matched pairs confirmed that the suicide and control groups did not differ in age, IQ, or number of Rorschach responses. In keeping with Blatt and Ritzler (1974) no attempt was made to control for previous suicide attempts in the control group. The only criterion was that at the time of the study none of the control patients was reported to have committed suicide.

Rorschach protocols were scored for presence of transparency (e.g., "a light bulb"), translucency (e.g., "a car"), and cross-sectional (e.g.,

"X ray") responses as described by Blatt and Ritzler (1974). Additionally, responses that were not clearly transparencies but that seemed to conform to Blatt and Ritzler's interpretation of transparencies as "an attempt to establish three-dimensional representations, but without the capacity to represent volume" (p. 282)—for example, "splattered paint"—were scored as criterial. All Rorschach protocols were scored independently by two judges.

When the number of transparency, translucency, and cross-sectional responses were totaled for each patient, the suicide group showed a significantly greater number of criterial responses ($M = 3.00$) than did the control group ($M = 1.78$); one-tailed t test for matched pairs, $t(13) = 2.33$, $p < .05$. The two patient groups were not found to differ when transparencies (including translucencies) and cross-sectional responses were analyzed separately.

These results replicate, in large part, the findings of Blatt and Ritzler (1974). That Blatt and Ritzler found differences between groups when analyzing transparency (and translucency) and cross-sectional responses independently while we found significant group differences only when combining these responses does not seem critical. Both classes of responses were seen by Blatt and Ritzler as exemplifying the same formal property—an inadequate representation of volume. Our findings, in cross-validating those of Blatt and Ritzler, provide evidence that a single sign on the Rorschach may be a useful predictor of suicide.

Roth and Blatt (1974), in considering why transparencies are given primarily by suicidal individuals, reasoned that this response reflected a loss or collapse of three-dimensional representation, paralleled by a loss of self-other differentiation, leading to the self and other becoming viewed as objects of aggression. This interpretation is consistent with the findings that suicidal individuals give transparency responses on the Rorschach; however, it does not explain specifically why patients who complete suicide give transparency responses more frequently than other patients who may threaten or attempt suicide.

We suggest an alternative model for understanding the association of suicide and transparencies. This model is admittedly speculative, but it is consistent with some clinical literature and is subject to empirical validation.

Since the characteristic that most obviously distinguishes completed suicides is that they are

responsible for their own death, our approach has been to consider the meaning of death for these individuals. In this regard, Morse (1973) has described suicide-promoting fantasies. In these fantasies, according to Morse, death is conceptualized as a means for satisfying important wishes, rather than an end in itself. A presupposition of suicide-promoting fantasies is that the individual will be alive after he/she kills himself/herself. Morse suggests that even though all humans are incapable of truly conceiving of their own death, suicides are distinctive in the degree to which they accept their after-death fantasies as real.

We suggest that transparency responses on the Rorschach (and, more generally, inadequate representations of volume) can be understood in the same terms as suicides' conceptions of death. Just as death seems to be viewed as a transitional phase rather than as a definite end, so too transparencies exemplify this same penetrable quality—An object is not represented as solid and bounded but as something insubstantial or pregnable.

At present, there is a dearth of systematic research assessing the conceptions of life and death held by suicidal and nonsuicidal individuals. Empirical assessment of the hypothesis of a relationship between transparencies on the Rorschach and attitudes toward death is one clear direction for research that would facilitate an understanding of the present findings and perhaps suggest further avenues of investigation.

Premorbid Social Competence Construct Generalizability Across Ethnic Groups: Path Analyses With Two Premorbid Social Competence Components

Raymond M. Costello

Department of Psychiatry, University of Texas Health Science Center at San Antonio
and Audie Murphy Veterans Administration Hospital, San Antonio, Texas

The stability across ethnic groups of interrelations among five variables was studied using path analysis. Certain findings involving four variables were consistent with theoretical expectations for the Anglo-American group but were reversed in the Mexican-American group. Methodological and theoretical implications are presented.

The stability across ethnic groups that is, Mexican Americans and Anglo Americans of interrelations among five variables: education, age at first psychiatric hospitalization, current age at admission, symptom severity, and behavioral adjustment while hospitalized, was studied using path analysis. Subjects were 14 male Mexican Americans and 14 male Anglo Americans admitted consecutively to a Veterans Administration hospital, studied treatment, and longitudinal outcome and standard deviations for Mexican Americans and Anglo Americans respectively were education = $MD = 11$ and $SD = 1.7$ and $MD = 12$ and $SD = 1.9$; current age = $MD = 31$ and $SD = 7.1$; symptom severity = $MD = 1.0$ and $SD = 1.4$; and behavioral adjustment = $MD = 0.6$ and $SD = 0.4$. The path model for symptom severity was compared across a series of four models of common variance of symptom severity. Behavioral adjustment was measured by rating scales on first psychiatric hospitalization, and was also analyzed as a function of the MA and Anglo groups. High scores reflect a negative score with good social skills.

Interrelations of interrelations within each variable were examined through path analysis. The path model for symptom severity was compared across a series of four models of common variance of symptom severity. Behavioral adjustment was measured by rating scales on first psychiatric hospitalization, and was also analyzed as a function of the MA and Anglo groups. High scores reflect a negative score with good social skills.

placed in a standard causal order, and a standard score transformation for each variable for each group preceded analysis. A correlation of .30 was required for significance. Ten bivariate correlations were decomposed. Nine of 42 Mexican-American coefficients and 10 Anglo-American coefficients were $\geq .30$. Significant relationships nonreplicable across ethnic groups, were observed between education and symptom severity; education and behavioral adjustment, and first hospitalization age and symptom severity. In each case the direction of the zero-order correlation, of the direct causal effect, and of the total causal effect was reversed across ethnic groups. Differences in magnitude of correlation were noted also. Significant relationships replicable across ethnic groups were observed between education and current age and first admission age and current age. Nonsignificant relationships were observed for the remaining five variable pairs.

As education and first admission age are two components of the premorbid social competence construct (Fogel & Phillips, 1961), this study has implications for psychosocial developmental theory. A successful developmental history (i.e., higher education and older age at first psychiatric breakdown) should be associated with a good prognosis (i.e., less severe symptomatology and better behavioral adjustment while hospitalized). Theoretical expectations were confirmed for Anglo Americans as three statistically significant bivariate relations within the Anglo group were of the proper sign, and none were inconsistent with theory (see Table 1). Yet, not only were these predicted relationships not found for the Mexican-American group, they were actually reversed in sign. Better educated Anglos tended

Note: MA = Mexican American; AA = Anglo American; X₆ = education; X₄ = age at first psychiatric admission; X₅ = current age; X₂ = alcoholism symptom severity; X₁ = Behavioral adjustment.

to report fewer alcohol-related symptoms and were observed to make better verbal and social contact with other patients than did poorer educated Anglos. Anglos who were older at first psychiatric admission tended to report fewer alcohol-related symptoms on current admission than did Anglos who were younger at first admission. The obverse was true for each phenomenon within the Mexican-American group.

One can only speculate about the meaning of this nongeneralizability. In the Anglo-American group, education is obviously an additional adaptational tool. In the Mexican-American group, primarily a low-socioeconomic laboring class group, however, education may have been as much an adaptational liability as an asset, as these more educated people may have been less likely to be satisfied in laboring occupations. Or, these Mexican Americans who were in a position to acquire a more advanced education may have experienced additional sociopsychological stresses not ordinarily encountered in their ethnic groups as a result of socioeconomic/occupational upward mobility.

With regard to experimental methodology in racial ethnic comparisons, techniques such as subject matching or analysis of covariance

would be inappropriate controls of extraneous subject characteristics variance if the matching variable/covariate(s) show ethnic unreliability, as was found in the present study.

The obvious conclusion is that when predictor or criterion variables (and the theory by which they are subsumed) derive from work on ethnically homogeneous or ethnically unspecified groups are to be used in work with groups of specified ethnic composition different from the derivation group, the variables must first be studied with regard to their freedom from ethnic bias (i.e., generalizability). Failure to do so may lead to distorted findings with possible social ramifications. Second, the pathanalytic formulation has good potential as an instructional device.

Effects of the Sex of Both Interviewer and Subject on Reported Manifest Dream Content

Russ B. Kremsdorf, Lucy J. Palladino, Douglas D. Polenz,
and Barbara J. Antista
Arizona State University

The present study examined the effects of the sex of both interviewer and subject on the reported content of dreams. Three male and three female interviewers each interviewed five male and five female subjects to elicit dream reports. In contrast to previous studies, no sex differences in the sexual content of dreams were found, although the dreams of males were more vivid, active, and aggressive. Opposite-sex pairing mobilized reports of conflict within dreams, whereas same-sex pairing increased the sexual content. These results support the hypothesis that environmental factors are influential in determining the dream content that is reported.

What is often thought to be common to waking fantasy processes and dreams is that they both involve the psychological transformation of stored information with a relative lack of attention to external input. However, Whitman, Kramer, and Haldridge (1964) maintain that the conditions present at the time of dream reporting are more potent factors in determining dream content than are dream recall processes. Although experimental sleep research has begun to study the more obvious effects of setting and presleep stress on the manifest content of dreams, relatively little attention has been given to the effects of the sex of the interviewer on the dream content that is reported.

Those studies that have investigated the sex of the experimenter in the areas other than dream research have found that this variable can influence such diverse phenomena as conformity and compliance, need affiliation, empathy, classroom learning, verbal conditioning, and experimenter bias. The sex of the interviewer has also been demonstrated to affect frankness, honesty, and enjoyment of an interview when discussing sensitive areas of communication. Such findings indicate the need to consider the sex of both participants both separately and in interaction, in areas of inquiry in which this variable has formerly been neglected.

Studies of dream content have commonly focused on the differences between the dreams of

male and female subjects. In the most well-known investigation, Hall and Van de Castle (1966) found dreams of males to be generally more active, to contain more male characters than female characters, to exhibit more aggression, and to involve more sexual content than those of females when dream diaries were submitted to a male class instructor. Similar results have been reported in the literature, though in almost every study of dream content male interviewers were used. There has been no controlled experimental attempt to assess the effects of the sex of both participants on the dream content reported.

The purpose of this experiment was to systematically examine the subsequent effects on reported dream content when male and female subjects were interviewed by either male or female interviewers. This design allowed for observing whether the differences generally reported between the dreams of male and female subjects might be related to the failure of these studies to use interviewers of both sexes. Special emphasis was given to those dream content ratings considered to reflect the most basic dimensions of the dream (Hauri, Sawyer, & Rechtschaffen, 1967) and most likely to reflect differences influenced by the sex of the participants.

The subjects were 30 male and 30 female undergraduate students enrolled in introductory psychology courses. Male subjects ranged in age from 17 to 30 years, with a mean age of 21.2 years. Female subjects ranged in age from 17 to 32 years, with a mean age of 19.9 years. Interviewers were three male and three female clinical psychology graduate students of approximately the same age and therapeutic experience.

Requests for reprints and for an extended report of this study should be sent to Russ B. Kremsdorf, Department of Psychology, Arizona State University, Tempe, Arizona 85281.

Each interviewer was randomly assigned five male and five female subjects and requested each subject to report the content of the last dream he/she could recall. After allowing the subject to complete the spontaneous dream report, the interviewer clarified any ambiguities. All interviews were audio recorded. Most of the dream rating dimensions used in this investigation were derived from the factor analytic study of dream ratings by Hauri et al. (1967). The six independent dream content dimensions were vivid fantasy, hedonic tone, active control, verbal aggression, physical aggression, and sexuality. Affect in the dream reports was also assessed by the content analysis scales developed by Gottschalk, Winget, and Gleser (1969). These dimensions were anxiety, hostility directed outward, hostility directed inward, and ambivalent hostility.

Because of the relatively good reliabilities obtained on this free-response material, all data analyses used mean ratings of the four raters. Overall, the dreams reported by male and female subjects did not differ in either the intensity or degree of sexual content. However, same-sex pairings of subjects and interviewers resulted in more sexual content, an interaction approaching significance, $F(1, 56) = 3.82, p < .10$. The dreams reported by male subjects were more vivid, $F(1, 56) = 6.76, p < .025$; active, $F(1, 56) = 4.58, p < .05$; and physically aggressive, $F(1, 56) = 4.36, p < .05$; than those of females. In addition, the dreams of males exhibited more overall subjective impact than the dreams of females, $F(1, 56) = 5.40, p < .025$. Opposite-sex pairing of subjects and interviewers resulted in dream reports that reflected greater anxiety, $F(1, 56) = 6.40, p < .025$; hostility directed inward, $F(1, 56) = 6.84, p < .025$; and ambivalent hostility, $F(1, 56) = 2.78, p < .10$.

In contrast to previous assertions, the results of this study argue against the assumption that biological differences between the sexes determine the degree of sexual content within dreams. En-

vironmental factors such as the sex of the individual to whom the dream is reported seem influential in the resulting dream report. It is difficult to determine whether the differences between these results and those of studies conducted over 20 years earlier are due to cultural changes in sex roles or to the fact that earlier studies used only male interviewers. The other differences found between the dream reports of males and females are consistent with similar comparisons made in a number of studies over the last 30 years. This does raise the question of whether some basic dream processes are somehow different between the sexes.

The results pertaining to opposite-sex pairing and dream reports support the assertion that to stimulate conflict for therapeutic purposes, one should expose the individual to a member of the opposite sex. However, these findings also suggest when sexual problems are the area of concern, pairing a client with a therapist of the same sex may facilitate discussion. Finally, the researcher of dream content and the clinician need to consider that the dream report that they collect is not immune to the effects of the setting in which it is reported.

Androgyny and Self-Esteem in the Upper-Middle Class: A Replication of Spence

Kevin O'Connor, David W. Mann, and Judith M. Bardwick
University of Michigan

A middle-aged upper-middle class sample was used in a replication of Spence, Helmreich, and Stapp's study of androgyny and self-esteem in an undergraduate sample. The earlier findings were largely replicated. Self-esteem scores for the men were substantially higher than those found by Spence et al., but the earlier relationships of androgyny, masculinity, and femininity with self-esteem received support. Implications of the demographic characteristics of the sample for the generality of current sex role and sex identity research are discussed.

Recent research on androgyny has focused on the relative adjustment of men and women classified as more or less masculine, feminine, or androgynous (e.g., Bem, 1975; Kaplan & Bean, 1976). These reports indicate that the healthiest individuals are not those who score at the extreme of their sex-appropriate distributions on masculinity-femininity scales. Instead, those classified as androgynous score highest on measures of adjustment and mental health (Bem, 1975; Carlson, 1971; Heilbrun, 1976; Spence, Helmreich, & Stapp, 1975).

The generality of this finding has been limited, however, by the demographics of the subjects—typically college undergraduates—used in these studies. In the present study, upper-income, middle-aged, Caucasian, suburban homeowners were studied, and their data were compared with those reported by Spence et al. (1975) in their study of college students. Thus, our research attempted to extend the generality of the theoretically important findings reported by Spence et al. in their work on androgyny.

Traditional sex role research considers masculinity and femininity as diametrically opposed clusters of attributes. Healthy individuals were considered to be those characterized by high gender-appropriate masculinity or femininity scores. As noted, contemporary work has taken the opposite view with high self-esteem predicted for the jointly masculine and feminine

individual regardless of sex (e.g., Bem, 1977; Spence et al., 1975).

Our purpose was to see whether our more traditional, established, conservative sample would produce the pattern of sex role attribute ratings and the relationship of androgyny with self-esteem reported by Spence et al.

Specifically, Spence et al. reported findings from several sets of analyses. We were concerned with the following:

1. Spence et al. compared the mean scores of men and women on each of their measures: sex role attribute ratings—endorsement of "valued" sex-typed attributes, measures of the willingness to describe "typical" men and women in sex stereotyped terms, a self-esteem scale, and a scale of agreement with feminist attitudes toward women. They reported significant sex differences in all but the self-esteem scores. We tested for sex differences using the same measures in our sample.

2. Spence et al. correlated their measures. They reported significant positive correlations between men's masculinity scores and use of masculine stereotypes and between women's femininity scores and use of feminine stereotypes. They reported that sex-appropriate sex role attribute self-ratings tended to relate negatively to feminism for men and women, but they found strong negative correlations between sex stereotyping and feminism. Finally, they found positive correlations between sex role attribute scores and self-esteem but no relation between self-esteem and feminism. We examined these correlations in our data.

3. Spence et al. placed the men and the women into groups based on their sex role attribute scores. For example, those above the

We gratefully acknowledge Mary Ellen Colten's substantive contribution to the work reported here. Requests for reprints should be sent to Judith M. Bardwick, Department of Psychology, University of Michigan, 529 Thompson, Ann Arbor, Michigan 48109.

median on masculinity were classified as high masculine, those below, low masculine. They crossed the dichotomized masculinity and femininity groups to produce a fourfold table for each sex. The cells were high masculinity-high femininity (defining androgyny), high masculinity-low femininity (traditional male), high femininity-low masculinity (traditional female), and low femininity-low masculinity (which Spence et al. call undifferentiated). Comparing the mean self-esteem scores of the four groups for each sex, they found that for each sex self-esteem means were highest in the androgyny cell and descended in the order given above.

We applied these procedures in our data to see whether this central aspect of Spence et al.'s findings would be replicated in our strikingly different sample.

Method

Procedure. Subjects were Caucasian men ($n = 43$) and women ($n = 48$) between 40 and 50 years old. All were members of an informal subdivision association who responded to a letter sent to members requesting volunteers for the study. The mean number of children in the sample was 3.26 per family; annual income for the sample ranged from \$50,000 to well over \$100,000. Many of the women were employed outside the home; and the men were employed in professional and executive positions.

The self-administered questionnaires were left at the subjects' homes and were picked up after two days during the fall of 1975. Self-esteem was measured by the Texas Social Behavior Inventory (TSBI); sex role attribute ratings and sex role stereotyping, by the Personal Attributes Questionnaire (PAQ); and degree of feminism, by the Attitude Toward Women Scale (AWS). Order of presentation was counterbalanced. All instruments are described in Spence et al. (1975) and were used as reported there.

Results

On the whole, sex differences in the data reflected those reported by Spence. The men in our sample described themselves as significantly more masculine than did the college men, $t(289) = 2.08$, $p < .05$. Unlike Spence's men, ours were no more prone to use sex role stereotypes than the women. And, in our sample as in Spence's, the women were only slightly (insignificantly) more profeminist than the men. Regarding self-esteem, our occupationally successful men scored significantly higher than the women, $t(89) = 2.35$, $p < .05$, who scored at the same level as all of Spence's subjects regardless of sex.

Similarly, correlations generally reflected relationships consistent with those of Spence, except that femininity was not related to self-esteem among the men. Masculinity and self-esteem were significantly correlated among men and women, $r(41) = .38$ and $r(45) = .77$, $ps < .05$; femininity and self-esteem correlated only among women, $r(45) = .46$, $p < .05$.

The relationship between self-esteem and masculinity reflects the vocational achievements of these men, having clearly met and surpassed the standards of competence embodied in the Spence et al. Masculinity scale. The interpersonal skills indexed in the Femininity scale seem not to contribute to self-esteem for these men, unlike the college sample.

Thus, two questions remained: (a) Could any of our samples be classified as androgynous? and (b) if so, Would the pattern of self-esteem means reported by Spence et al. hold?

The answer to both questions was a straightforward yes. Our results were in close agreement with Spence. The androgynous men and women were highest in mean self-esteem, followed, within each sex, by masculine, feminine, and undifferentiated groups.

Overall, our data lend support to and extend the generality of the work of Spence et al. Principally, androgynous self-descriptions did occur reliably in our sample and androgynous self-descriptions predicted the highest levels of self-esteem for men and women. The high esteem and masculinity scores of the men may well reflect the broader opportunities to test their competence that are available neither to their spouses nor to college students.

MICROCOUNSELING: Innovations in Interviewing, Counseling, Psychotherapy and Psychoeducation (2nd Ed.) by Allen E. Ivey, Univ. of Massachusetts, Amherst, and Jerry K. Worell, Univ. of Nebraska Medical Center, Omaha. Foreword by Bernard G. Guernsey, Jr. (Contributors) The new edition of this book includes updated research on the microcounseling model, chapters on the cross-cultural and cross-racial implications of interviewing and counseling, and material illustrative of how microcounseling skills are used by various types of therapists. A section on operational definitions has also been added. '78, 624 pp., 13 il., \$14.00

INTRODUCING NEUROPSYCHOLOGY: The Study of Brain and Mind by Stuart J. Freedman, Univ. College, Cardiff, Wales. The study of consciousness and other enigmas of human life are discussed in this book to explain how the mind and behavior are related to the underlying machinery of the brain. An introduction of basic methods and systems is followed by chapters on the effects of brain injury and disease, the split-brain condition, the human, the cerebral cortex, the infant brain, neurological processes in psychiatric illness, development of technology for control of the brain, and other topics. Students, practitioners and researchers in psychology are among those who will find this book to be enlightening and provocative. '78, 236 pp., 12 tables, \$13.75

BEHAVIOR THERAPY IN CLINICAL PSYCHIATRY: Decision Making, Procedure and Outcome by Ernest G. Poser, McGill Univ., Montreal, Quebec, Canada. Foreword by H. J. Eysenck. This text considers the application of behavior conditioning principles to mental health problems. It explores specific fears, social withdrawal and socially disapproved behavior. Illustrative case studies are included. '78, 244 pp., 4 il., 1 table, \$13.50

THE MALTREATED CHILD: The Maltreatment Syndrome in Children—A Medical, Psychological and Social Guide (3rd Ed.) by Vincent J. Carrozza, New York Foundling Hospital, New York City, and Douglas J. Besharov, United States National Center of Child Abuse and Neglect, Washington, D. C. Foreword by Loretto Bernard. This edition covers the problems of child maltreatment; their nature, causes and extent; and the means to deal with them. '77, 176 pp., 11 il., \$12.50

CAREER DEVELOPMENT AND COUNSELING OF WOMEN edited by L. Sunny Hansen, Univ. of Minnesota, Minneapolis, and Rita S. Rapoza, Wilson Learning Corp., Eden Prairie, Minnesota. (46 Contributors) Articles are included on psychological and environmental variables which affect female development and which have an impact on their decisions, not only about work, but also about their life roles with respect to family, leisure and community. Occupational socialization, planning and negotiating for multiple roles, assessment of career interests, cross-cultural perspectives of female career development, and other topics are examined. '78, 672 pp., 57 tables, \$24.75

NEXUS PSYCHOTHERAPY: Between Humanism and Behaviorism by Kenneth Urial Gutsch, Univ. of Southern Mississippi, Hattiesburg, and Jacob Virgil Ritenour, II, Jackson, Michigan. Foreword by Howard S. Rosenblatt and Harold H. Dawley, Jr. The common ground between humanism and behaviorism is explored as it relates to emotions, behavior, values and motivation. It is a unique approach which will provoke new understandings in psychotherapy as it presents methods by which such understandings can be implemented. '78, 196 pp., 15 il., 16 tables, \$14.75

CEREBRAL LOGIC: Solving the Problem of Mind and Brain by Charles W. Needham, Neurological Associates of Tucson, Tucson, Arizona. In its inquiry into the neurophysiology of consciousness, this book considers equally the disciplines of neurology, philosophy, and psychology. A discussion of the general nature of the mind-brain problem is followed by a look at the origin of mentalistic language and its applicability to cerebral logic. '78, 232 pp., 1 il., \$12.75

THE POWER OF POSITIVE REINFORCEMENT: A Handbook of Behavior Modification by Judith Elbert Favell, Western Carolina Center, Morganton, North Carolina. This handbook systematically surveys the entire process of behavior modification. Initial chapters explain preoperational procedures such as the specification and definition of target behavior. The remainder of the book details the actual application of behavior modification, including positive and negative reinforcement, token systems, and complex behavior training. '77, 288 pp., 1 il., 1 table, \$9.75

AHSEN'S EPT

Description: Ahsen's Eidetic Parents Test (EPT) elicits eidetic images of parents, in the mind of the subject, in 30 situations. Each response is a triadic experiential unit — an image(I), a somatic response(S), and a meaning(M). A precise test for localizing personality structures, somatic and emotional patterns and psychological themes in the form of images which do not change unless transformed through therapeutic

Indications:

Uses: Easily administered within one hour (brief) or longer (comprehensive), if desired. A structured interview which elicits valid developmental and personality data, also an initial diagnostic instrument or therapy process, for use with adults and children. Full instructions for psychological report writing.

"A methodological advance."

— *American Journal of Psychiatry*

"An important addition to the fear inventories and reinforcement schedules currently in use...a rapid and effective method."

— *Behavior Therapy*

"An exciting and ingenious way of getting at conflict areas and providing a rich source of material for therapeutic sessions...A new and intriguing device for personality assessment."

— *Contemporary Psychology*

"Therapeutic as well as diagnostic and fact finding." — *The International Journal of Clinical and Experimental Hypnosis*

NEW

from the APA Insurance Trust A TOTAL MEDICAL INSURANCE PACKAGE and MORE for APA members

A new, medical insurance package for APA members is ready

Five new programs of coverages and deductibles — flexible enough to
meet the differing needs of APA members — offer you and your
colleagues a total medical insurance package.

More than supplementary health-care protection, this package offers.

BASIC MEDICAL — Program A

For the APA member who does not have other medical insurance, Program A provides up to \$5,000 of coverage for each medical condition, subject to a \$50 deductible and an 80/20 co-insurance provision. This provision and the deductible help reduce premium and maintain the low cost group rate available to APA members.

COMPREHENSIVE MEDICAL — Program B

The solution for APA members who desire a combination of Basic and Major Medical Insurance is Program B. While essentially the same as Program A, this Program provides a lifetime maximum benefit of \$250,000.

MAJOR MEDICAL — Programs C, D, E

The programs for APA members who only want to supplement their current health-care plans are the Major Medical Programs. With lower premiums, these offer a range of deductibles — \$10,000, \$15,000, \$25,000 — to suit individual needs.

The medical insurance package you need is ready. And there's more.

HOSPITAL INDEMNITY INSURANCE

With Hospital Indemnity you can safeguard against the additional expenses of hospitalization — the babysitter fees, long distance phone bills, special nursing charges — the expenses that are not covered by your program of health insurance.

Because Hospital Indemnity provides up to \$100 a day, every day that you are hospitalized. A full year of benefits — cash benefits you can use any way you want — with no waiting period before these benefits begin. Hospital Indemnity can help fill in the gaps in your health-care plan.

THE TOTAL MEDICAL INSURANCE PACKAGE AND MORE.

For more information, fill out the coupon below and mail it today.

INSTRUCTIONS TO AUTHORS

Style of manuscripts. Manuscripts must be prepared in the style described in the *Publication Manual of the American Psychological Association* (2nd ed.). Instruction on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors should submit manuscripts in triplicate and should keep a copy to guard against loss.

Abstracts. Manuscripts of regular articles must be accompanied by an abstract of 100-175 words. Manuscripts of brief reports must be accompanied by an abstract of 75-100 words. All abstracts must be typed on a separate sheet of paper.

Brief Reports. The *Journal of Consulting and Clinical Psychology* will accept Brief Reports of research studies in clinical psychology. The procedure is intended to permit the publication of soundly designed studies of specialized interest or limited importance which cannot now be accepted as regular articles because of lack of space. Several pages in each issue will be devoted to Brief Reports, published in the order of their receipt without respect to the dates of receipt of the regular articles. Most Brief Reports appear in the first or second issue to go to press following their final acceptance.

An author who wishes to submit a Brief Report:

1. Sends the Brief Report, limited to two printed pages and prepared according to the specifications given below.

2. Agrees not to submit the full report to another journal of general circulation.

Specifications. The Brief Report should give a clear, condensed summary of the procedure of the study and as full an account of the results as space permits.

To ensure that a brief report does not exceed two printed pages, follow these instructions for typing: (a) Set typewriter to a 48-space line. (b) Type text. (c) Count all lines except abstracts, title, and by-line, including acknowledgments. If you have exceeded 185 lines, shorten the material. (d) If your brief report barely exceeds 75 lines (one printed page), try to edit to 75 lines exactly. Reports slightly exceeding one page will be edited for length in order to use space economically.

In Brief Reports, headings, tables, and references are avoided, or, if essential, must be counted in the 75 lines. This journal no longer requires an extended report, but, if one is available, each Brief Report must be accompanied by the following footnote:

Requests for reprints and for an extended report of this study should be sent to John Doe (give the author's full name and address).

The footnote should be typed on a separate sheet and *not* counted in the 75-line quota.

Effects of Experimental Manipulation of Self-Disclosure on Group Cohesiveness

Barry J. Kirshner

Jewish Social Service Agency of Metropolitan Washington
Rockville, Maryland

Robert R. Dies and Robert A. Brown

University of Maryland

Self-disclosure in 8-hour experiential groups was systematically controlled by providing detailed audiotaped instructions and illustrations through a series of structured exercises. Two levels of self-disclosure (level of intimacy) were established. Four eight-person heterosexually balanced groups were exposed to encounter group tapes that instructed them to share intimate feelings and experiences. Examples of high self-disclosure and openness were presented to clarify the instructions. In contrast, four comparable groups were conducted by encounter group tapes that furnished only moderate levels of personal disclosure and interpersonal sharing. Groups in both the high and low intimacy conditions received the same set of exercises and differed only in the instructions and accompanying behavioral examples. Results of the study indicate that higher levels of disclosure produced greater group cohesiveness, as hypothesized, on four separate measures of the dependent variable. Findings on three different types of self-report instruments were corroborated by an unobtrusive behavioral measure of cohesiveness.

The effects of group cohesiveness in therapy and encounter group contexts have now been widely documented. Yalom (1975), in his popular text on group psychotherapy, surveyed evidence demonstrating that group cohesiveness is an important determinant of positive therapeutic change and produces many results that are considered to mediate successful therapy outcome. Yalom saw this variable as sufficiently important to list it as 1 of 11 curative factors in group therapy, and to devote an entire chapter to it. Other re-

viewers of the experiential group literature have arrived at similar conclusions regarding the importance of cohesiveness (Goldstein, Heller, & Sechrest, 1966). Clarification of the factors that produce cohesiveness could be enormously useful in designing more helpful group experiences.

Although the consequences of group cohesiveness have been relatively well established, its determinants remain less clear. Goldstein et al. (1966) offered a set of hypothesized variables that ostensibly enhance group cohesiveness, including pregroup expectancies, intergroup competition, temporary inclusion of a "deviant plant," resolution of subgroup differences, and verbal reinforcement; only a few studies have tested these inferences. Other investigators have suggested that group composition (Yalom & Rand, 1966) and leadership style (Yalom, 1975) may be important precursors to cohesiveness. One variable that has particular relevance for the present investigation is the role of self-disclosure.

This article is based on the first author's doctoral dissertation submitted in partial fulfillment of the requirements for the PhD degree at the University of Maryland. Dies and Brown served as co-chairman for this research. Computer support was provided by the University of Maryland Computer Science Center.

The authors wish to thank the other committee members for their contributions: Steven Brauth, Bruce R. Fretz, and Charles Gelso.

Requests for reprints should be sent to Barry J. Kirshner, Jewish Social Service Agency, 6123 Montrose Road, Rockville, Maryland 20852.

Yalom (1975) contends that the group therapist greatly influences the self-disclosure level of group members, and that this in turn contributes to cohesiveness and intermember attraction. The leader, as technical expert, prompts members to share personal material and reinforces self-disclosure through a variety of verbal and nonverbal acts. As a model-setting participant, the leader shares personal feelings, reactions, and experiences, and thereby paves the way for similar risk taking among group members.

There is a small body of research relating self-disclosure to various measures of group cohesiveness and interpersonal attraction. Certner (1973) found that subjects had a greater liking for those from whom they had received more intimate divulgements. Analogously, group members who are higher disclosers early in group life have been found to assume high popularity in the group (Hurley, Note 2). In addition, research by Bean (1972) and Query (1964) indicated that groups high in interpersonal openness were also high in cohesiveness.

Unfortunately, the link between self-disclosure and cohesiveness has occurred mainly within the context of correlational research. One exception is a study by Ribner (1974), who manipulated self-disclosure by means of a pregroup contract. Even though Ribner successfully demonstrated that an initial contract emphasizing self-disclosure did indeed influence subsequent group cohesiveness, his study was limited by the brevity of his group sessions (1 hour), the small variability of topical categories discussed within his groups, and by the analogue nature of his study.

The present investigation was an attempt to extend Ribner's (1974) findings to an actual experiential group setting in which participants had convened for the explicit purpose of improving self-understanding and interpersonal awareness. This study also endeavored to extend the correlational and clinical evidence regarding the presumed association between self-disclosure and cohesiveness by subjecting this relationship to experimental scrutiny.

Method

Subjects

Subjects were recruited from undergraduate classes in psychology and education at the University of Maryland. The students were given a brief description of the research project and were informed that the groups would be 8-hour tape-led interpersonal growth groups designed to facilitate awareness of self and others. Participation was strictly voluntary, without the additional incentive of extra course credit. The final sample consisted of 64 subjects divided into eight groups of 4 males and 4 females each. Half of the groups were assigned to the high intimacy condition and half to the low intimacy condition.

Procedure

All groups met for one 8-hour extended session. Structure was provided by an audiotape similar in format to the *Encountertapes* developed by Berzon (e.g., Berzon, Reisel, & Davis, 1969). The tape presented detailed instructions for the group exercises and furnished illustrations of the behaviors expected in the structured group interactions. The instructions and examples were used to systematically control for levels of intimacy or self-disclosure.

Groups in the high and low intimacy conditions received the same set of exercises and differed only in the instructions and accompanying examples. In the low intimacy condition, instructions and illustrations referred to levels of self-disclosure that were nonpersonal to mildly personal, whereas in the high intimacy condition the self-revelations were moderately to highly personal or private. The sequence of structured activities on the tape was as follows:

Introduction and warm-up exercises (35 minutes). All groups began with a brief introduction explaining the nature of the group. Subjects were informed that after each exercise an unrecorded segment of tape would continue to run, corresponding to the time allotted for the exercise. Following this introduction the group members participated in three warm-up exercises to help them become acquainted with each other and to share some relatively nonthreatening experiences. The structured activities were the name game, trust walk, and negotiated combat (Stevens, 1971).

Top secret (75 minutes). This was the first activity to experimentally manipulate the level of intimacy within the groups. Participants were requested to write an anonymous "secret" about themselves on a slip of paper. Members in the low intimacy condition were asked to furnish secrets or personal information that did not have to be highly revealing. Examples were provided on the tape, for example, "I am a junior and still haven't decided on a major yet." In the high intimacy condition, the secrets were to be private and difficult to share with most people. Examples such as "There were times when I felt so miserable I wondered if life was worth living

anymore" were presented on the tape. Group members were then instructed to place their secrets in the top of a box and then after all the statements had been enclosed and the box was shaken to pull out a secret from the bottom. The box was specially constructed for this task and, unknown to group members, contained a false bottom with 12 pre-selected statements to further insure the proper level of intimacy early in the group. Participants were told that several additional secrets were placed in the box beforehand to further insure anonymity. In this way group members would not get suspicious when their secret was not read. Later questioning by the experimenter indicated that the deception was effective. The deception involved in using contrived secrets initially concerned the investigators. However, the particular secrets used were comparable to those generally obtained with this technique in encounter groups, and similar to those furnished by the present subjects. Furthermore, subjects were not disturbed or resentful when the manipulation was revealed, and both groups reported the experience to be meaningful and personally rewarding. So even though the deception was effective, it did not seriously detract from the richness of the experience. After retrieving a statement, members were instructed to take turns reading them to the group and to consider each one in turn for 5 minutes. After all members had read their secrets, a 20-minute group discussion of their reactions ensued. The tape provided guidelines and an illustration of how to conduct a group discussion. This portion of the tape served to further reinforce the experimental manipulation of intimacy by providing either low or high levels of personal group conversation.

Self-disclosure and cohesiveness measures (15 minutes). All group participants completed two questionnaires at this point in the group. These were a self-disclosure measure, willingness to disclose, and a measure of group cohesiveness (Gruen, 1965). These instruments are described in detail below.

Dyadic interaction (90 minutes). Group members were instructed to choose a partner and then to engage in a 10-minute conversation focused on a topic provided by the tape. Following the conversation, participants were told to choose new partners for another 10-minute discussion on a different topic furnished by the tape. This procedure continued until all group members had met with each other. The topics were selected from material rated as being either high or low in intimacy by Taylor and Altman (1966).

Lunch (30 minutes). Participants were instructed in advance to bring lunch for themselves as well as something to share with the rest of the group.

Problem solving task (30 minutes). This exercise is described by Pfeiffer and Jones (1970) and is used to study sharing of information and leadership behavior in small groups. Briefly, a problem is presented to the group, and each member is supplied with certain pieces of information necessary to solve the problem. The task was included to provide a mechanism for getting the group working together again after lunch.

Self-disclosure exercise (110 minutes). This exercise was similar to top secret, but at this point, the disclosures were no longer anonymous. Groups in the high and low intimacy conditions were again given differential instructions and concrete examples to control for level of intimacy. Then, members took turns reading and commenting on their statements, and when they had finished there was a group discussion based on guidelines furnished by the tape.

Group fantasy (20 minutes). This exercise was presented as a "recreational" activity for the group (Stevens, 1971). There was no attempt to manipulate intimacy.

Self-disclosure and cohesiveness measures (20 minutes). The Willingness to Disclose and Gruen questionnaires were readministered along with two additional cohesiveness measures. The first was an index of cohesiveness developed by Schutz (1958), and the second was the Comfortable Interpersonal Distance Scale (Duke & Nowicki, 1972). These are described below.

Closing and review of the group experience (25 minutes). The final portion of the group experience was used to review what happened and to end with a group hug, in which members gathered close together and silently hugged one another as a group. They were told to terminate the hug whenever they pleased. The group experience was then concluded, and the experimenter met with the participants to debrief them and to provide them with the opportunity to express their reactions to the experience.

Experimental Measures

Self-disclosure was systematically manipulated at several key points in the sequence of structured activities presented on the tape. A check on the effectiveness of the manipulation was essential, since the hypotheses regarding the link between self-disclosure and cohesiveness could not be adequately tested without a clear demonstration that self-disclosure was indeed systematically controlled. Two different measures were used to verify the efficacy of the manipulation.

The first measure was the Willingness to Disclose Questionnaire, which was administered to group participants after the initial manipulation of intimacy in the top secret exercise. The questionnaire was specifically constructed for this investigation and contained 38 statements of various levels of intimacy across a variety of categories. Group members were required to indicate all items that they would be willing to discuss in their experiential group at that time (roughly 2 hours into the session). The items were selected from a pool of statements rated for intimacy by Taylor and Altman (1966). The sum of the intimacy values for the items selected yielded the Willingness to Disclose score.

The second measure of self-disclosure was a modified version of a rating procedure developed by Dies (Note 1) to assess intimacy level of tape-recorded segments of group interaction. Content was judged along a 7-point continuum ranging from impersonal

and event-oriented conversations on the low end of the scale to very private feelings, reactions, and experiences on the high end. In the present study, two segments of the group interactions were tape recorded—the top secret exercise and the self-disclosure exercise—providing portions of early and late group interaction, respectively. Three-minute samples were taken from the middle of the first, second, and last thirds of each segment, yielding three early and three late ratings for each group. These 3-minute samples were coded and randomized before being rated by two trained judges whose scores were averaged to determine the final rating. Interrater reliability was .80 on the 48 samples evaluated in this study.

Several measures of the dependent variable, cohesiveness, were incorporated into this investigation, based on prior research which suggests that cohesiveness is a multifaceted variable capable of being evaluated from a variety of perspectives (e.g., self-report, behavioral). The first was the Gruen (1965) measure, administered along with the Willingness to Disclose Questionnaire after the top secret exercise. This scale contains four group tasks and six product outcomes for each. Participants were instructed to select the outcome that they thought their group would produce if they engaged in the task. The Gruen scale was the only measure of cohesiveness repeated in this study.

Three additional measures of cohesiveness were used, however. A scale described by Schutz (1958) has been shown to produce fairly consistent validity. It is a seven-item Guttman cumulative index to assess favorability of attitudes toward the group and its members. A third measure of cohesiveness, the Comfortable Interpersonal Distance Scale (Duke & Nowicki, 1972), was developed to assess interpersonal closeness. This measure is in the form of a diagram with seven calibrated lines radiating from a central point. Subjects were instructed to imagine themselves at the center of the diagram and to respond to the other group members as if they were moving toward them along the protruding radii. They were to draw a line on the corresponding radius indicating how close they would allow that particular member to advance. The final measure, the group hug, was included to provide an unobtrusive behavioral measure of cohesiveness. This measure was based on research by Dies and Greenberg (1976), which indicated that physical contact was related to here-and-now feelings of interpersonal closeness. The group hug came at the end of the experiential session and was timed; the duration of the hug was considered an index of cohesiveness.

Results

Separate analyses of variance were computed for each of the independent and dependent variables examined in this study. Results of all variables were analyzed using individual subject scores except for the tape

ratings and group hug, which were designed as total group measures.¹

Self-Disclosure (Independent Variable)

The analysis of self-disclosure was essentially a check on the effectiveness of the experimental manipulation. Two separate self-disclosure scores were available. The Willingness to Disclose Questionnaire was administered twice to the group. The second measure was the judges' ratings of self-disclosure from the tapes: Scores from both early (top secret) and late (self-disclosure exercise) group interaction were available. A repeated measures analysis of variance was carried out for the self-disclosure scores. The results summarized in Table 1 indicate that the treatment effects on both variables were highly significant, thus confirming the efficacy of the experimental manipulation.

Group Cohesiveness (Dependent Variable)

Results summarized in Table 1 indicate that higher levels of intimacy or self-disclosure produced greater group cohesiveness on all four dependent measures ($p < .01$). The Gruen instrument was administered at two different times to the group and was therefore analyzed with a repeated measures analysis of variance. The other three measures were administered at the conclusion of the 8-hour marathon. Results of the three self-report measures were confirmed by the unobtrusive behavioral measure of cohesiveness, the group hug.

Development Over Time

Analysis of the Willingness to Disclose instrument indicated that self-disclosure significantly increased over time ($p < .01$), and the tape ratings reflected a trend ($p < .10$) in the same direction. Analysis of the Gruen

¹Group analyses were, in fact, calculated for all variables, since it could be argued that individual scores within groups were not truly independent observations. These group analyses supported the individual analyses in virtually every case. Only the individual analyses are included here to simplify the discussion and presentation of results.

scale, the only measure of cohesiveness repeated in the investigation, also demonstrated a statistically reliable increase as a function of time ($p < .01$). The means and corresponding F values for these analyses appear in Table 1.

The repeated measures design also indicated a significant interaction effect between willingness to disclose and treatment condition ($p < .01$), and between cohesiveness and treatment condition ($p < .01$). Tukey's method for multiple comparisons was computed to test the differences between all means. In terms of willingness to disclose, there was a significant difference between treatment conditions, both early and late in the group. However, the increase over time was much greater for the low intimacy condition groups than for those groups in the high intimacy condition. However, although differences in cohesiveness were significant between high and low conditions at both times in the group life, the greater increase over time on the Gruen measure was found in the high disclosing condition. Apparently, self-disclosure and cohesiveness showed different developmental trends as the groups progressed.

Discussion

Group practitioners agree on the importance of self-disclosure in the formation of meaningful interpersonal relationships. Yalom (1975), for example, theorized that as disclosures proceed in the group, the entire membership gradually increases its level of involvement, responsibility, and obligation to one another: "If the timing is right, there is nothing which will commit an individual to a group more than to receive or to reveal some intimate secret material" (p. 360). Results of the present investigation strongly support this hypothesized relationship between self-disclosure and cohesiveness.

The terms *self-disclosure* and *cohesiveness* have been defined in a variety of ways. With respect to self-disclosure, this study focused on only one of its many salient dimensions, namely, level of intimacy. The influence of other parameters—breadth, frequency, time, and content orientation—were not addressed, nor have they received sufficient attention by

other researchers. Yet it is conceivable that these factors are just as influential, or perhaps even more so, than level of intimacy.

Similar arguments could be offered for the concept of "group cohesiveness." Prior researchers have often equated cohesiveness with attraction or liking, whereas the present study defined cohesiveness in several ways: liking, physical contact, comfort with inter-

personal distance, and estimates of group productivity. Although these measures were intercorrelated in this investigation, the moderate level of the correlations suggests that they are not identical scales. A multimethod approach in future studies of group cohesiveness is strongly recommended.

The specific mechanisms accounting for the empirical association between disclosure and cohesiveness have received comparatively scant attention in the literature. Altman and Taylor (1973), however, have suggested that the relationship between self-disclosure and liking (one aspect of cohesiveness) is mutually reciprocal and based on interpersonal rewards and costs. Self-disclosure could be rewarding and thereby enhance liking if it implies that the receiver is trusted (Worthy, Gary, & Kahn, 1969); the more intimate the disclosure, the more rewarding it is for the person receiving it (Certner, 1973). Moreover, disclosures are rewarding if they reveal attitude similarity between the individuals involved (Bersheid & Walster, 1969), or if they imply that the discloser likes the other person (Walster, 1965).

Other possible mechanisms for relating self-disclosure and cohesiveness pertain more to costs than to rewards. For example, highly intimate revelations, rather than being simply rewarding, could make the disclosers feel vulnerable. Cohesiveness may develop as a source of protection for members to insure that their "secrets" are kept within the group. As Yalom (1975) stated,

the receiver . . . is likely to consider himself charged with certain responsibilities or obligations to the discloser. He generally responds to the disclosure by some appropriate comment . . . and then reciprocates with some disclosure of his own. The receiver now, as well as the original discloser, is vulnerable, and a deepening relationship usually continues, with the participants making slightly more open and intimate disclosures in turn until some optimal level for that relationship is reached. (pp. 359-360)

Clarification of the mechanisms involved in the disclosure-cohesiveness relationship is of considerable theoretical and practical importance. For example, group experiences designed to enhance cohesiveness would be dramatically different if the major determinants of cohesiveness were associated with

rewards rather than with interpersonal costs (e.g., attitude similarity as opposed to anxiety over vulnerability).

Even without clarification of these mechanisms, however, group practitioners who wish to enhance group cohesiveness may apparently do so by concentrating on methods of increasing self-disclosure. A variety of procedures can facilitate this process. As a first step, the practitioner can pay careful attention to group composition. Evidence suggests that groups composed of members with high interpersonal skills (including self-disclosure) may be more cohesive (D'Augelli, 1973). The group leader can also introduce a pregroup contract to influence members' expectancies regarding the group experience. A variety of role-induction techniques have been studied including preparatory interviews, written contracts, audiotaped and filmed examples of "appropriate" client behavior, and interpersonal skills practice. A review of this literature indicates that these procedures are effective in enhancing levels of self-disclosure, interpersonal feedback, and other positive member behaviors in both therapy and brief encounter group contexts (Bednar, Melnick, & Kaul, 1974).

Once the group sessions have begun, the clinician can continue to augment member self-disclosure. One method, used in the present study, is to use verbal and nonverbal structured group exercises. Egan (1976), for instance, presented a series of structured activities specifically designed to foster intimate sharing among group participants. Dozens of other compendiums of similar techniques are now available on the market. Some research suggests that these structured techniques can heighten feelings of intermember closeness and willingness to take risks within the group setting (Dies & Greenberg, 1976). The group leader can also increase self-disclosure among group members by adopting a relatively transparent style of leadership (Dies, 1977a), by reinforcing such openness among group participants (Dies, 1977b), and by facilitating the establishment of relatively clear group norms (Lieberman, Yalom, & Miles, 1973).

There were differences between the rates of increase in self-disclosure and cohesiveness.

Even though cohesiveness increased over time, it apparently did not directly follow the growth in willingness to self-disclose. Consequently, one cannot conclude that the increment in readiness to self-disclose over time produced the increased cohesiveness. It is possible that the production of high levels of intimacy early in the group, as opposed to a gradual development over time, was the crucial factor leading to heightened cohesiveness. This interpretation received some earlier support from Hurley's (Note 2) findings that individuals high in disclosing behavior early in their group achieved high popularity later in their group. However, this issue is not entirely clear in the present study, since there were possibly ceiling effects on the willingness to disclose measure.

The form of the relationship between self-disclosure and cohesiveness and the question of which comes first pose important theoretical and pragmatic questions. Nevertheless, this study suggests that we can systematically enhance the level of these variables within our groups and thereby increase the probability of positive therapeutic outcomes.

Subtle-Obvious Ratings of MMPI Items: New Interest in an Old Concept

William L. Christian, Barry R. Burkhart, and Malcolm D. Gynther
Auburn University

Previous attempts to devise subtle-obvious ratings for Minnesota Multiphasic Personality Inventory (MMPI) items have been too gross, restricted to certain scales, or have failed to consider the perspective of the psychologically naive inventory user. To correct these deficiencies, university students were asked to rate all 566 MMPI items, answered true and false, on a 5-point subtle-obvious scale. Reliability of ratings was assessed via responses to duplicate items; the reliability coefficients were .98 for items answered true and .91 for items answered false. Males and females gave very similar ratings; correlations were .94 and .90 for true and false items, respectively. Mean ratings for all subjects showed that MMPI scales *F* and *Sc* were most obvious and that *Mf* and *Si* were least obvious with regard to pathology. The correlation between obviousness ratings and desirability ratings was $-.78$. Analysis of previous measures of the subtlety-obviousness dimension in terms of the present item ratings indicate that previous measures did not adequately represent the very subtle or very obvious extremes of the distribution. Further research with these ratings should demonstrate whether empirically derived inventories with their subtle items are, in fact, useful tools for personality assessment.

Responses to personality inventories are determined by instructional sets, stylistic features, and certain other characteristics of item content, that is, social desirability, sentence structure, ambiguity, and subtlety. Content of Minnesota Multiphasic Personality Inventory (MMPI) items was considered relatively unimportant for many years, partly as a function of Meehl's (1945) influential article. However, the pendulum has swung the other way; more and more attention is now being paid to content (Jackson, 1971; Koss & Butcher, 1973; Wiggins, 1966).

Measures of desirability have long been available (Edwards, 1957; Heineman, 1960; Messick & Jackson, 1961) for those who wish to explore the relations between MMPI item endorsement and desirability. Sentence structure of MMPI items has been analyzed (Wiggins, 1964), and ambiguity ratings are available (Harris & Baxter, 1965). (All of these

"itemmetric" data are available in Dahlstrom, Welsh, & Dahlstrom, 1975.) However, subtle-obvious ratings (despite appearances to the contrary) have not been developed. This lack is curious when one considers that the subtlety-obviousness distinction has been an integral part of the controversy over empirical versus intuitive internal test construction strategies.

There have been three efforts to deal with the subtle-obvious issue: X and O classification (Meehl & Hathaway, 1946), Wiener's (1948) subtle-obvious keys, and Duff's (1965) subtle-intermediate-obvious categories. X items are those that relatively few normals endorsed in the scored direction. Content of these items is usually undisguised and obviously pathological. O items are those endorsed by a majority of normal subjects, but they are endorsed by an even higher percentage of clinical patients (and consequently scored in the direction of pathology). Content of these items is heterogeneous and not especially indicative of emotional disturbance. Wiener and Harmon (Note 1), using a rational-intuitive

Requests for reprints should be sent to Barry R. Burkhart, Department of Psychology, Auburn University, Auburn, Alabama 36830.

procedure, divided all MMPI items into those to which endorsement clearly indicated emotional disturbance and those to which emotional disturbance was not indicated by endorsement. Subtle and obvious keys were actually developed only for the *D*, *Hy*, *Pd*, *Pa*, and *Ma* scales (cf. Dahlstrom, Welsh, & Dahlstrom, 1972). Duff (1965) asked graduate students to identify the clinical scale from which an item was drawn and its keyed response. He used the 162 items from the *Hy*, *Pd*, and *Sc* scales plus 34 items from other clinical scales and 30 items not included on any clinical scale. Items whose scales and pathological responses were identified by no more than 10% of the judges were assigned to the subtle category, items identified by 11%–50% of the judges were assigned to the intermediate category, and items correctly placed by at least 50% of the judges were assigned to the obvious category.

Cronbach (1970), in discussing the MMPI, stated that "separate scoring of subtle and transparent items is emphatically needed" (p. 532). He pointed out that if subtle and obvious keys for the different scales were available, it would be possible to determine where the discriminating power lies. If the subtle keys proved to be invalid or the obvious items carried most of the discriminating power, as suggested by the work of Duff (1965) and Koss and Butcher (1973), the whole criterion-keyed empirical approach to test construction would be called into question. From the point of view of psychometric theory, the most important aspect of this research is the provision of data whereby these issues can be investigated in a more comprehensive manner than previously possible.

No investigator has used standard scaling procedures to determine mean subtle-obvious ratings of all MMPI items. In this study, such ratings were obtained from individuals relatively naive with respect to psychological inventories. Although college students, as a group, tend to be more defensive than men and women in general and, consequently, are more likely to perceive items as containing pathological content, they are more representative of those to whom the inventory is

typically administered than are graduate students or professional psychologists.

Method

Subjects

One hundred thirty-eight undergraduate students enrolled in introductory psychology sections served as subjects. The subjects were divided into three groups, each containing 25 males and 21 females.

Procedure

The first group of subjects rated 387 MMPI items, namely, Items 1–283, answered true, and the first 104 of the 209 items keyed false on the clinical scales answered false. The second group rated Items 284–566 answered true and the 105 remaining items keyed false on the clinical scales answered false. The third group of subjects rated the other 357 items answered false. Subjects were instructed to read each item carefully and to decide how clearly each item was indicative of a psychological problem. Very obvious items were to be assigned a rating of 5; obvious, a rating of 4; neither obvious nor subtle, a rating of 3; subtle, a rating of 2; and very subtle, a rating of 1.

Mean ratings of each item by males, females, and males and females combined were computed. Mean obviousness scores for standard MMPI scales were determined. Relationships between male–female ratings and desirability–obviousness ratings were evaluated by correlational analyses. The mean obviousness values of the X and O items; Wiener's (1948) subtle and obvious items; and Duff's (1965) subtle, intermediate, and obvious items, were calculated using our mean item ratings. Percentages of items in the MMPI clinical scales that fell into each of the five rating categories also were calculated.

Results and Discussion

Analyses of the ratings of the duplicate items in the MMPI showed very high agreement between the groups of judges. The product-moment correlation for the duplicate items answered true was .98 ($n = 14$) and for the duplicate items answered false was .91 ($n = 5$).¹ Means and standard deviations for the subtle-obvious ratings of all MMPI items answered true and false are contained in

(text continued on p. 1184)

¹ Although there are 16 duplicate items in the MMPI, the reliability coefficients are based on less than the full 16 items, because in dividing the items for rating by the groups of judges, some of the duplicate items were not rated by two groups of judges.

Table 2
*Percentage of Items in Subtle-Obvious Categories for
 Minnesota Multiphasic Personality Inventory Clinical Scales*

Scale ^a	Very subtle	Somewhat subtle	Neither subtle nor obvious	Somewhat obvious	Very obvious
<i>Hs</i>	03	09	58	30	00
<i>D</i>	08	28	33	25	05
<i>Hy</i>	08	30	32	30	00
<i>Pd</i>	04	20	38	26	12
<i>Mf</i>	42	28	26	05	00
<i>Pa</i>	02	20	20	27	30
<i>Pt</i>	00	04	31	58	06
<i>Sc</i>	01	00	32	46	20
<i>Ma</i>	06	30	39	15	08
<i>Si</i>	12	34	35	17	00

^a The rating weight for an item was assigned within any particular scale in correspondence to the way that item was scored in the scale being considered. Therefore, if an item was scored false for that scale, then the false value was used, and if scored true for that scale, then the true value was used.

Table 1. It is interesting to note that when all MMPI items were rated as true, 333 of them were defined as subtle (i.e., mean value of less than 3.00) and 233 were defined as obvious (i.e., mean values greater or equal to 3.00).

Although mean values were calculated separately for males and females, space limitations allowed only for presentation of the combined ratings. It should be noted, however, that the correlations between male and female raters were very high; the product-moment correlations for true and false items were .94 and .90, respectively.

The combined mean obviousness ratings for the standard MMPI scales, ordered from most obvious to most subtle, were: *F* = 3.70; *Sc* = 3.64; *Pa* = 3.52; *Pt* = 3.47; *Hs* = 3.13; *Pd* = 3.13; *D* = 2.94; *Ma* = 2.82; *Hy* = 2.81; *Si* = 2.64; *L* = 2.41; *K* = 2.28; and *Mf* = 2.21. (The rating weight for an item was assigned within any particular scale in correspondence to the way an item was scored in the scale being considered. Therefore, if an item was scored false for that scale, then the false value was used, and if scored true, then the true value was used.)

With the exception of *Pa* and *D*, there is a perfect linear relationship between the mean obviousness scores for the clinical scales and the amounts of *K* correction added. This relationship between the suppressor *K* variable

and obviousness of item content of the scales is understandable. Although the ordering of the scales suggests that both *Pa* and *D*, but especially *Pa*, share the item characteristics associated with the need for the addition of *K*, McKinley, Hathaway, and Meehl (1948) found that the addition of *K* did not increase the predictive power of *D* and *Pa*. Explanations of this apparent anomaly are that (a) correction items were included on the *D* scale to minimize elevations on psychiatric cases whose primary diagnosis was not depression, and (b) more than 20% of the *Pa* items were subtle in character. (Cf. Table 2 for a comparison of *Pa*, *Pt*, and *Sc* with regard to percentages of very subtle and somewhat subtle items.) The correction items and the subtle items both function as *K*; hence, the addition of some fraction of *K* to these two scales was unnecessary, as *K* did not improve discriminative efficiency.

Table 2 shows the percentages of items in each of the subtle-obvious categories for each of the MMPI clinical scales. Examination of this table shows that *Pa* contains the highest percentage of items rated as "very obvious." However, if the two "obvious" categories are combined, one finds that *Sc* with 66% and *Pt* with 64% rank first and second on this dimension. Duff (1965) found that *Sc* contained a higher proportion of obvious items than *Hy* or *Pd*; percentages were 40, 22, and 6,

respectively. *Mf* contains far more items rated as "very subtle" (i.e., 42%) than any other scale. If the two "subtle" categories are combined, it can be seen that *Mf* ranks first and *Si* second in subtlety. There was also considerable variability in the neutral category; it is somewhat surprising to find that over half of the *Hs* items were considered neither obvious nor subtle, especially in view of the fact that this scale has been considered as a marker variable for obviousness (cf. Wiener, 1948).

The obviousness ratings for all subjects were compared with the desirability ratings of Messick and Jackson (1961). Since Messick and Jackson's ratings are for items answered true only, only our ratings of true responses were used. The product-moment correlation was $-.78$ ($p < .001$), which suggests that the subtle-obvious dimension and desirability have much in common. However, the relationship is not high enough to substitute desirability for obviousness ratings or vice versa.

Analysis of previous subtlety-obviousness measures in terms of the subtle-obvious ratings obtained in the present study demonstrated that the different procedures produced results that are superficially similar. Mean ratings of X and O items² were 3.16 and 2.04, respectively. Statistical analysis showed that these differences were highly significant, $t(565) = 3.58$, $p < .001$; however, it should be noted that the mean value of the X items was in our "neither subtle nor obvious" category. Wiener's (1948) subtle items ($M = 2.44$) were significantly more subtle than his obvious items ($M = 3.45$), $t(221) = 2.06$, $p < .05$, but neither set was extreme in terms of our ratings. The mean ratings of Duff's (1965) subtle, intermediate, and obvious items were 2.69, 3.38, and 3.60, respectively. Analysis of variance indicated that these means were significantly different, $F(2, 185) = 26.06$, $p < .001$. Further post hoc tests showed that the mean ratings of Duff's subtle items were significantly more subtle than the intermediate items, but the intermediate items were not significantly different from the obvious items. Here again it might be pointed out that the mean value of Duff's subtle items falls in our "neither subtle nor obvious"

category. The similarity then is more apparent than real, inasmuch as these previous rating schemes for the most part yielded values that tend to cluster in the neutral or obvious categories. Very subtle and very obvious items, in particular, seem to be strikingly underrepresented.

Jackson (1971) has argued that "those items are the best which are clearest and which contain referents about which people agree" (p. 239). Goldberg and Slovic (1967) compared responses to abstract designs with responses to items designed to measure achievement and affiliation and demonstrated that "only scales built from items of the highest face validity had significant cross-validity" (pp. 466-467). Duff (1965) found an inverse relationship between MMPI item subtlety and item discriminating power. Koss and Butcher (1973) showed that the MMPI items that characterized crisis situations displayed content clearly relevant to the particular situation (e.g., "The future seems hopeless to me" for the depressed-suicidal crisis). We have used these subtle-obvious ratings to show that subtle items are highly resistant to faking (Burkhart, Christian, & Gynther, 1978) and that endorsement of subtle items is characteristic of psychologically minded subjects (Burkhart, Gynther, & Christian, 1978). However, the most pressing problem is to determine the amount of trustworthy information provided by the endorsement of obvious and subtle items or keys. It may be that obvious/subtle keys for certain scales provide useful information, whereas obvious/subtle keys for other scales do not. In that case, one would want to use the valid obvious and subtle keys to maximize the discriminative power of the inventory. However, if further research confirms Duff's (1965) contention that subtle keys contribute no or very little information, development of a new inventory containing all obvious items (or an MMPI revised toward the same end) would be in order.

² These classifications are given in Appendix A of Dahlstrom, Welsh, and Dahlstrom (1972). It should be noted that the O items found in this appendix are not the same as the zero items used by Seeman in several studies (e.g., Wales & Seeman, 1969).

Factor Structure of the SCL-90 in a Psychiatric Population

Norman G. Hoffmann and Peggy B. Overall
University of Texas Medical Branch, Galveston

The responses of an unselected psychiatric outpatient sample to the SCL-90, a self-report checklist of symptom complaints, were factor analyzed using a principal components procedure. Varimax rotation yielded five interpretable factors for which factor scores were derived. Results were compared with earlier studies using symptom checklists on selected outpatient diagnostic groups. Implications for future work with self-report symptom checklists are discussed.

Most clinical research in psychiatry over the past decade has relied on symptom and behavior ratings made by professional observers to describe psychopathology and to measure therapeutic response (Lorr, Klett, & McNair, 1963; Overall, 1974). There are numerous instances, however, for which it would seem desirable to assess how patients perceive their own states. The Minnesota Multiphasic Personality Inventory (MMPI; Hathaway & McKinley, 1967), the Psychological Screening Inventory (PSI; Lanyon, 1970), and other pencil-and-paper inventories have proved useful for description and classification of psychopathology, but as a general rule they have not appeared as useful as might be desired for the assessment of change. This is perhaps because such instruments are designed to measure more stable personality traits rather than states. A self-report psychiatric symptom checklist that was developed out of the more general item pool of the Cornell Medical Index (CMI) has been proposed as an instrument capable of measuring clinical states subject to therapeutic intervention and has undergone preliminary tests in psychopharmacology research. Originally called the Hopkins Symptom Check List (HSCL), the instrument has undergone sev-

eral revisions (Derogatis, Lipman, Rickels, Uhlenhuth, & Covi, 1974).

Investigations have considered the factor structure of the original 58-item HSCL (Derogatis, Lipman, Covi, & Rickels, 1971, 1972; Lipman, Covi, Rickels, Uhlenhuth, & Lazar, 1968; Lipman Rickels, Covi, Derogatis, & Uhlenhuth, 1969; Mattsson, Williams, Rickels, Lipman, & Uhlenhuth, 1969; Williams et al., 1968). Four to six factors have been reported to account for the bulk of the variance. Although the labels assigned to the factors have varied, depression and anxiety factors have consistently emerged. Other factors frequently noted are represented by items dealing with somatic concerns, obsessive-compulsive themes, and interpersonal sensitivity.

The SCL-90, a 90-item revision of the HSCL, was created by the addition of 32 items concerned with symptoms of more serious psychopathology. Content of the added items concerns psychotic symptoms, paranoid ideation, phobic anxiety, and hostility (Derogatis, Lipman, & Covi, 1973). Thus, the SCL-90 would appear to have potential for use in the assessment of psychopathology in a more general psychiatric population.

Lipman, Covi, and Shapiro (1977) accomplished a factor analysis of the SCL-90 using data collected in a study involving chemotherapy of depressed patients. They identified eight factors, which they labeled as Interpersonal Sensitivity, Phobic Anxiety, Retarded Depression, Anger-Hostility, Somatization, Obsessive-Compulsive, Agitated Depression, and Psychoticism. Thus, they ob-

This study was supported in part by Department of Health, Education, and Welfare Grant 5 RO1 MH14675-09.

tained factors similar to those found most often in analyses of the 58-item HSCL plus a psychoticism dimension defined predominantly by the added items.

A major concern that motivated the present investigation arises from the fact that the bulk of all previous factor analyses of the HSCL as well as the SCL-90 have focused on patients selected for symptoms of anxiety and/or depression. Diagnostic differences have been shown to affect the interpretation of factors on the HSCL (Derogatis et al., 1972), and similar results could be expected with the SCL-90.

This may be a particular problem when the intent is to use the SCL-90 for assessment of psychopathology in more general psychiatric populations. Factors that appear to be relatively independent in a restricted sample may be too highly correlated to be identified as separate factors in a more heterogeneous sample. Conversely, factors that are clearly present in a general psychiatric population may be absent in a highly selected, homogeneous sample. The purpose of the present article is to document the structure and statistical properties of the SCL-90 in a clinic population unselected for diagnosis and representative of the general psychiatric outpatient population seen in public facilities such as medical school clinics.

Method

The SCL-90 was administered to 358 new patients seen in the Adult Psychiatry Outpatient Clinic at

Figure 1. Eigenvalues for primary factors.

the University of Texas Medical Branch. The sample was unselected with the exception that an eighth-grade education and professed ability to read the newspaper was required. The examiner also heard the subjects read aloud the two sample items and respond to them. Verbal informed consent was obtained from each patient for the statistical research use of the test data. Demographic and diagnostic information was recorded to provide additional description of the sample.

The factor analysis used a principal components procedure, and the significant factors were rotated by the orthogonal normalized varimax method.

Factor scoring keys were defined to include the items that were found to project most highly on each of the rotated factors. To be included in a factor score, an item was required to have its highest loading on that factor. No items with a loading less than .350 were considered for factor scoring. Factor scores were then calculated for each subject by summing the values of the items included in the factor. The reliabilities of a single total score of pathology and the individual factor scores were estimated using coefficient alpha (Cronbach, 1951), which is an internal consistency statistic that assesses the average of all possible split-half coefficients. The intercorrelations among the factor scores were calculated to evaluate the extent to which the factors really represent distinct or independent aspects of psychopathology.

Inspection of the demographic variables indicates that the patients seen in this clinic are predominantly younger women from the lower socioeconomic classes. Almost 75% of the sample consisted of women, and over half of the patients were under 30 years of age. Ethnically, the group contained blacks and whites with a distinct minority of Mexican Americans who comprised 10% of the sample. An approximation of social class using educational and work levels in the "Two-Factor Index of Social Position" (Hollingshead, Note 1) resulted in almost 60% of the patients being classified into the lowest social class and only 13% of the sample placed into the three upper social classes.

In terms of psychopathology the current sample seems to differ substantially from those in previous studies of the HSCL and SCL-90. Although over 40% of the patients had a diagnosis of depression, many of those would not be candidates for inclusion in drug studies. Many cases involved personal crises as precipitating events. Indeed, 34% of all the patients seen were not prescribed any medication. Furthermore, the sample includes individuals with a variety of neurotic complaints, and personality problems as well as thought disorders, as is reflected in the fact that 16% of the patients were diagnosed as schizophrenic or schizoaffective.

Results

The pattern of eigenvalues obtained from the principal components analysis is shown in Figure 1. These results are presented to em-

phasize the prominence of a single general factor in the SCL-90 responses of patients in this outpatient clinic population. The first unrotated factor accounted for 6.45 times as much variance as the next largest and more than twice the variance of the next six factors combined. This suggests that in this patient population, the SCL-90 tends to measure a unitary global complaint factor and that the self-report complaints of the patients are not highly differentiated with respect to the more specific factors the instrument may be capable of measuring.

The display of the eigenvalues also suggests that five factors account for variance greater than the random scree level. The fifth factor is the first to depart in any measure from the nearly flat linear function that might be expected from random noise.

In point of fact, rotated solutions for 3-8 factors were examined, and the five-factor solution provided the most interpretable results. When only 3 or 4 factors were rotated, the content of the items loading on each factor appeared heterogeneous, making interpretation of the factors less clear. Conversely, when more factors are rotated, the later factors tend to fragment into interpretatively similar factors.

The five normalized varimax factors that were clearly defined and interpretable are Depression, Somatization, Phobic Anxiety, Functional Impairment, and Hostile Suspiciousness. Of the 90 items, 81 met the criteria of a loading greater than .350 and could be placed in one of the factors.

Examination of the item content found within each factor provides a straightforward picture of the basis for the interpretation of the factor. The factors identified here tend to agree well with those reported by Lipman et al. (1977). The bulk of the items in their two depression factors project highly on the single depression factor found here. The Somatization and Phobic Anxiety factors are almost identical to Lipman et al.'s in terms of the items with highest loadings on the respective factor. These three factors were found to be the most prominent in this unselected sample of patients.

The other factors, while not showing such a striking similarity to those obtained by previ-

ous investigators, do tend to have considerable overlap of items. The Functional Impairment factor in the present study most closely corresponds to the obsessive-compulsive factor in the Lipman et al. (1977) analysis. The bulk of the items in the Anger-Hostility and Psychoticism factors of the earlier study project on the Hostile Suspiciousness factor in the present study. The Interpersonal Sensitivity factor in the Lipman et al. study had highest loadings for six of its seven items evenly divided between the Depression and Hostile Suspiciousness factors described here, and it is the only Lipman et al. factor not related primarily to only one factor of the present study.

Factor scores were calculated by summing the responses to the sets of items indicated under each factor. Reliability of the factor scores was estimated using coefficient alpha, which is derived from internal consistencies among the item responses and is equivalent to the mean of all possible split-half reliability coefficients. The reliabilities for the five factor scores were .94, .90, .89, .83, and .94, respectively, indicating the high degree of consistency among the items that compose each factor.

The correlations between the factor scores were quite high, ranging from .504 to .747. This state of affairs is not unexpected in view of the very large eigenvalue associated with the first unrotated factor from the primary analysis and the fact that many items with their highest loading on one factor also had substantial projections on other factors. Even though it might have been possible to use only those items that projected onto only one factor, this would have greatly reduced the number of items available for the factor scales.

The total score on the SCL-90 was reliable and highly correlated with each of the factors, further suggesting that a single global score might well be used as an index of psychopathology or psychological discomfort. The correlations of the total score with the five factors were .928, .746, .831, .789, and .906, respectively. The Spearman-Brown split-half reliability between odd and even items was .976, and the alpha coefficient for the total test was .975.

For comparison, the factors defined by Lipman et al. (1977) were scored for this general outpatient sample. Intercorrelations among the eight Lipman factor scores ranged from .407 to .853, and the correlations of these factors with the total score ranged from .769 to .910. Again, it is apparent that at least some of the factors are not clearly distinguishable in the responses of patients in this general psychiatric clinic population. If one were to correct for attenuation due to measurement error, some of these correlations would approach unity. These results support our own in suggesting that scores that are ostensibly associated with distinct aspects of psychopathology are, in fact, measuring the same thing in this type of psychiatric clinic population.

Discussion

The rotated factors derived from the SCL-90 responses of a sample of unselected psychiatric outpatients appeared quite similar to the responses of depressed and/or anxious patients selected in previous psychopharmacology studies. These similarities were noted despite the fact that the current sample included a substantial proportion of individuals who were not deemed in need of medication, as well as more disturbed individuals who were taking antipsychotic medication. The checklist items and format would appear to tap some common dimensions in a broad range of patients.

The Depression, Somatization, and Phobic Anxiety factors seem to be the most clearly defined in the present study and are most consistent with other work on the HSCL and SCL-90. Of the three, the Somatization factor appears to be a slightly more independent dimension, in that its correlations with the other factors scores and the total test score tend to be lower.

Despite consistencies with factor structures in previous studies, the large proportion of variance accounted for by the first unrotated factor and the high intercorrelations among the factors raise some concerns that the instrument measures more of a general complaint or general discomfort dimension than distinct dimensions of psychopathology. Because of this, we have reservation about the

use of factor score profiles as has been proposed. More investigation is needed to determine whether factor scores of the SCL-90 do indeed produce profiles that provide a basis for differentiating different aspects of pathology.

Whether or not the SCL-90 can be used for specialized interpretations, such as distinguishing between anxiety and depression, our results indicate definite promise for the instrument as a global index of psychopathology or psychological distress. The total score derived from the summation of all items can be recommended for such a purpose. The inclusion of the SCL-90 in psychopharmacological studies seems quite appropriate for furthering the understanding of the properties of the instrument and exploring its construct validity. The evolution of better criterion measures is certainly needed in drug evaluation research, and the SCL-90 may hold promise as such a measure.

Notice on Author Alterations

Effective January 1979, the procedure for billing authors for alterations will change. Authors of articles in APA journals are customarily charged for alterations on proofs that result from (a) authors' errors or omissions in the manuscript and (b) changes that result from authors' failure to review the edited manuscript or the proof. Until now, alteration charges have been determined by the number of lines affected by changes requested and have been based on 1974 printing rates. Beginning with the proofs for the first issues of 1979, authors' alterations will be determined not only by the number of lines affected but also by the number of figures and pages affected and will be based on current printers' rates.

This change in alteration billing is being made so that alteration charges will more closely reflect the actual cost of changes requested and may mean larger alteration bills for some authors. Authors are reminded that alteration charges apply only when changes are made on proofs and that *there is no charge* for changes made at the manuscript stage.

Internal-External Expectancies and Health-Related Behaviors

Bonnie R. Strickland
University of Massachusetts, Amherst

The present article is a review of research on internal-external (I-E) locus of control expectancies and health attitudes and behaviors. The theoretical background of the I-E construct is described. Topics covered include I-E in relation to health knowledge, precautionary health practices, reactions to physical disorders, psychological responding, psychological disturbances, and responses to psychological treatment. Some problems and issues are also noted.

Health concerns and health costs constitute a social problem of enormous magnitude in this country (APA Task Force on Health Research, 1976). Estimates of numbers of individuals with symptoms severe enough to warrant attention with respect to treatment range as high as 75% of the general population (Mechanic, 1972). The cost of medical care is the fastest growing item in the U.S. consumer price index, close to \$100 billion annually, and it is expected to more than double over the next 5 years ("Health-Cost Crisis," 1977). For good reason, individuals appear to be increasingly concerned not only with recognizing and attending to debilitating symptoms but also preventing the occurrence of illness or accident. The rewards to those persons who remain free of disease or disability are, of course, not only financial but include enhanced physical and emotional well-being as well. The findings from a broad range of studies demonstrating a generally greater adaptive functioning for those persons holding internal as opposed to external expectancies (Strickland, Note 1, Note 2) have clear implications with respect to health.

Earlier versions of this article have been presented at meetings of the American Psychological Association in 1972 and 1973 and at the XV InterAmerican Congress in 1974. The writing of these articles and the present one were supported in part by funds available through the National Institute of Child and Human Development, Grant 08952.

Requests for reprints should be sent to Bonnie R. Strickland, Department of Psychology, University of Massachusetts, Amherst, Massachusetts 01003.

The internal-external control of reinforcement (I-E) dimension is an expectancy variable couched within Rotter's social learning theory (Lefcourt, 1976; Phares, 1976; Rotter, 1954; Rotter, Chance, & Phares, 1972; Strickland, 1977). Simply stated, I-E refers to the degree to which an individual perceives the events that happen to him/her as dependent on his/her own behavior or as a result of luck, chance, fate, or powers beyond one's personal control and understanding. Assessment of I-E expectancies is via questionnaires, of which the Rotter I-E scale (Rotter, 1966) has been the instrument of choice for most ongoing research with adults. Several multidimensional instruments to assess I-E have been devised (Collins, 1974; Gurin, Gurin, Lao, & Beattie, 1969; Levenson & Miller, 1976), and some researchers have developed I-E measures specific to health (Kirscht, 1974; Wallston, Wallston, Kaplan, & Maides, 1976). Results of research conducted with the various instruments suggest that beliefs about internal versus external control are related in significant and even dramatic ways to health-related behaviors. The purpose of the present article is to review these relationships across several broad areas of health, ranging from prevention to susceptibility to remediation of physical and psychological dysfunctions.

The Theoretical Framework

The implication that I-E expectancies are related to the facilitation of health behaviors

is derived from social learning theory. Rotter (1954; Rotter et al., 1972) postulated behavior to occur as a function of expectancy and reinforcement within a specific situation. If a situation is novel or ambiguous, then an individual will depend on generalized expectancies that have served him/her in the past. More specific expectancies are used when the aspects of the situation are straightforward or routine. The I-E dimension is a *generalized* expectancy that occurs when individuals have learned that events are contingent or non-contingent on their behavior. Individuals holding internal expectancies are more likely than externals to take responsibility for their actions (Davis & Davis, 1972; Phares, Wilson, & Klyver, 1971) and to attribute responsibility to agents who activate chance (Hochreich, 1972; Phares & Wilson, 1972; Schiavo, 1973; Sosis, 1974). In performance task situations, internals are perceptually alert and attentive (DuCette & Wolk, 1973; Lefcourt, Gronnerud, & McDonald, 1973; Lefcourt & Wine, 1969; Wolk & DuCette, 1974) and appear to gather and process information effectively for problem solving (Davis & Phares, 1967; DuCette & Wolk, 1972; Pines & Julian, 1972). Research on social action (Gore & Rotter, 1963; Levenson & Miller, 1976; Pawlicki & Almquist, 1973; Sanger & Alger, 1972; Strickland, 1965) suggests that individuals who believe that events are related to their own behaviors are more likely than persons trusting fate or powers beyond their control to take steps to change aversive life situations. Phares (1976, p. 78) proposed that the cognitive and motivational aspects of the I-E dimension lead internals to a superior position in exerting power and control over their environment. If this is the case, then I-E expectancies may have significant impact in relation to health maintenance, a most important personal concern for many of us. Our parents and ourselves are enjoying a longer life span, with the accompanying infirmities of age, than has been true in the past. Even in good health, we are daily bombarded by the public media with information about the likelihood of disease occurring from such ordinary events as breathing city air and eating bacon. We are constantly urged to improve our health by losing weight, jogging, and engaging in all

those inviting, energetic activities designed to enhance our physical functioning. When we do experience physical or emotional distress, professional health care is more readily available to us than it has been in the past, and most of our friends and acquaintances have advice and their own favorite home remedies to share. One would expect that internals, in contrast to externals, would be more sensitive to health messages, would have increased knowledge about health conditions, would attempt to improve physical functioning, and might even, through their own efforts, be less susceptible to physical and psychological dysfunction.

Health Knowledge and Precautionary Measures

As early as 1962, Seeman and Evans found evidence that hospitalized patients with tuberculosis who were internal as assessed by an early I-E measure, with intelligence controlled, knew more about their disease than their matched external counterparts. The medical staff also rated internal patients higher in objective knowledge about tuberculosis than externals. In wards in which information was difficult to obtain, internal patients were significantly less satisfied with the flow of information than externals. The Wallstons and their colleagues (Wallston, Maides, & Wallston, 1976; Wallston, Wallston, Kaplan, & Maides, 1976) have also found that internals who value their health are more likely than others to collect information about disease and health maintenance when alerted to possible hazards, such as hypertension.

Following the growing concern in the 1960s about a link between cigarette smoking and cancer, numerous studies were conducted which suggested that individuals who were not smokers or individuals who were able to stop smoking were more internal than individuals who smoked (Coan, 1973; James, Woodruff, & Werner, 1965; Mlott & Mlott, 1975; Steffy, Meichenbaum, & Best, 1970; Straits & Sechrest, 1963; Williams, 1973; Platt, Note 3). These results have not always been replicated (Danaher, 1977; Lichtenstein & Keutzer, 1967), but taken together they do suggest that individuals with internal rather than ex-

ternal expectancies are more likely to take action to improve their health habits, particularly when faced with evidence that needed changes may result in improved physical functioning.

In a study of inoculation against influenza, Dabbs and Kirscht (1971) reported that college students who were assessed as internal on eight "motivational" variables were more likely than externals to have been inoculated, although internals on eight "expectancy" variables were not likely to have taken the shots. In other words, subjects who said that they were motivated to exert control in relation to health behavior did indeed take precaution against susceptibility to an infectious disease. Subjects who simply reported expectancies about contingencies between behavior and events were not differentiated according to having received flu shots. In a large-scale study with high school students, Williams (1972a) found that internal students reported greater use of seat belts when riding in an automobile than externals. These students also reported themselves to be significantly more likely to engage in preventive dental care, that is, to go to the dentist for checkups and maintenance even when teeth or gums are not sore or hurting (Williams, 1972b). Sonstroem and Walker (1973) found internal college males to hold more positive attitudes toward physical exercise and cardiovascular fitness than externals; these internal students were also more likely to participate in voluntary exercise.

In other research designed to investigate preventive health practices, Balch and Ross (1975) tested 34 females and reported internal beliefs to be predictive of both success in and completion of an overweight treatment program. Wallston, Wallston, Kaplan, and Maides (1976) found 22 female subjects in weight reduction programs consistent with their specific I-E beliefs about health to be more satisfied with treatment. Results of weight loss for subjects in congruent conditions were in the expected direction, although they failed to reach significance. Other experimenters have not been able to relate I-E to attempts at weight loss (Bellack, Rozen-sky, & Schwartz, 1974; Manno & Marston, 1972; Tobias & MacDonald, 1977), although

some reported overweight subjects to be external, a finding also reported by O'Bryan (1972).

At least two studies suggest that females who are internal are more likely than external females to practice birth control effectively (Lundy, 1972; MacDonald, 1970). However, Harvey (1976) assessed almost 200 female college undergraduates as to their reliance on safe (pill, intrauterine devices) versus risky (condom, rhythm, etc.) birth control methods and found no differences as a function of I-E expectancies. Segal and DuCette (1973) reported that middle-class white high school females who became pregnant were more external than control subjects; lower class, black, high school females who became pregnant were more internal. The authors suggested that pregnancy has different meanings for these populations. At that time, in the upper-class group, pregnancy might have been an undesirable event, and internal students would have been expected to take precautions against pregnancy. Pregnancy may have been more acceptable among the lower-class group and for some students might even have been a source of pride and success. If these assumptions are correct, then the discrepant I-E predictions make sense. Obviously, a number of complex factors enter into any decision, or lack thereof, about pregnancy. However, the I-E variable appears to be a promising one in relation to predicting the use of birth control, especially if goals of family planning and rationale for use of birth control can be specified.

With some exceptions, the bulk of the reported research on I-E and precautionary health practices lends credence to the expected theoretical assumptions that individuals who hold internal as opposed to external expectancies are more likely to assume responsibility for their health. Internals appear to attempt to maintain their physical well-being and to guard against accidents and disease to a greater extent than individuals who hold external expectancies. As would be expected within Rotter's theory, internals *who value their health* (reinforcement value) seek more information about health maintenance, and when stricken with a disorder

they appear to learn more about the disease that afflicts them. Other specific and generalized expectancies as well as situational contingencies would also be expected to interact with what is likely a complex relationship between I-E and precautionary health practices.

Reactions to Physical Disorders

When a person is faced with a chronic handicap or a debilitating illness, do I-E expectancies play any part in an individual's reaction to this situation? MacDonald and Hall (1971) asked healthy college students how they might respond to various physical handicaps in regard to social relationships and feelings about themselves. External rated physical disabilities as more debilitating than did the internals, who apparently anticipated less severe consequences of handicaps. But, what happens in real life? Lipp, Kolstoe, James, and Randall (1968) investigated the responses of handicapped and normal subjects to pictures of disabled people. The handicapped subjects suffered a variety of disabilities including amputation, paralysis, fractures, arthritis, and congenital deformities. Normal subjects were of approximately the same age and sex as the handicapped group and were matched on the basis of responses to the James I-E scale. Slides of disabled and normal persons were presented tachistoscopically to all subjects. As the investigators had hypothesized, disabled subjects took significantly more trials to recognize the disability slides than the normal subjects. Of interest to the present article are their findings of an interaction between three levels of I-E and the disabled/nondisabled dichotomy. The external disabled individuals were less denying of disability, as measured by recognition time of disability slides, than the internals, including those subjects whose scores fell in the middle I-E ranges. The investigators suggested that the internals are more threatened and hence more denying of disability than the externals.

Several other studies have been conducted investigating I-E in relation to threat to ascertain if internals and externals do respond differently. Phares, Ritchie, and Davis

(1968) provided subjects with either positive or negative feedback, which ostensibly resulted from their answers to a number of personality tests. Consistent with a denial model, externals, as assessed by the Rotter scale, recalled significantly more of the evaluative material, both positive and negative, than did internals. Internals did, however, demonstrate a greater willingness to engage in remedial behavior to confront their alleged problems. Another investigation by Houston (1972) gives additional information about the differential influence of I-E beliefs in regard to response to stress. Houston told one group of subjects that they could avoid electric shock in an experimental condition by not making mistakes on a subtest of the Wechsler Adult Intelligence Scale. Another group was told that there was no way to avoid shock. Subjects who perceived that they had some control over the shock reported less anxiety but actually evidenced greater physiological arousal than the no-control group. Although they did not report more distress, internal subjects showed an increase in heart rate significantly greater than did externals across both conditions. Evidently the internals were more aroused in the control of shock condition, but they denied their anxiety about the situation. Externals may have found it easier to "accept" the threat of shock and resign themselves to the situation. These results, of course, raise implications about the relation of I-E beliefs to a host of psychological findings on "perceived control" (Glass & Singer, 1972). I-E beliefs may have direct relevance, for example, to the Type A and Type B behavior patterns that Glass (1977) described. Glass wrote that Type A individuals, who sound strikingly like internals, appear to be engaged in a struggle for control and try to develop strategies for coping with uncontrollable stress. This continued attempt at mastery of life events, however, takes a tragic toll in that these individuals appear to be more prone to coronary heart disease.

Aside from studies on reactions of individuals to perceived threat, numerous investigations with persons who have actually suffered some traumatic event have been conducted. Blind children (Land & Vineberg,

1965), children with cerebral palsy (Egglund, 1973), and children with severe reading problems (Strickland & Hill, Note 4) have all been assessed as more external than comparable, nonhandicapped children. Jones (1974), however, investigated orthopedically disabled children and found no relationship between I-E beliefs and degree of mobility. Wendland (1973) tested 80 males, ages 18-35, with muscular skeletal impairment. Subjects who had been disabled less than 1½ years were significantly more external than subjects disabled 3 years or longer. Wendland suggested that disabled individuals have a tendency to expect increased direction from external forces during the initial period following disability onset.

Bruhn, Hampton, and Chandler (1971) compared a group of 36 male hemophilics, ages 12 and over, with a control group of normals. They found that overall, the hemophilic group was more internal than normal controls. But, within the hemophilic group, a marginally severe group was significantly more external than either a mild or a severe group. These investigators suggested that the marginally severe hemophiliac views his clinical state as unpredictable and is more dependent on external cues to determine his well-being. Goldstein (1976) also compared 24 long-term male hemodialysis patients with 22 male patients, all of whom were recovering from minor medical problems. The hemodialysis sample patients obtained significantly higher denial and externality scores than the nonhemodialysis control subjects.

A number of studies that are investigations of attempts to influence health care, once disabilities occur, are available. Weaver (1972) found that internal patients with severe kidney disorders who were using dialysis machines to stay alive were significantly more likely than matched externals to comply with diet restrictions and to keep scheduled appointments. Internal patients hospitalized with spinal cord injury had higher self-concepts and reported themselves to be less depressed than matched externals (Dinardo, 1972). Those internals who scored high on the repression side of Byrne's Repression-Sensitization scale showed the best adjustment, and external sensitizers showed the

poorest adjustment to spinal cord injury. However, Bulman and Wortman (1977) found no differential I-E predictions in a sample of 24 paraplegics or quadraplegics. Ireland (1973) attempted to investigate participation in treatment in relation to I-E beliefs among pulmonary emphysema patients. Ratings were difficult to obtain, and no clear findings emerged. He did find, however, as noted earlier, that internal patients knew more about their disorder than externals, even with intelligence controlled.

Presurgical external patients report more anxiety than matched internals (Lowery, Jacobsen, & Keane, 1975), and, following abdominal surgery, internal female patients are more likely to attempt to influence postoperative care in relation to obtaining more analgesics than external patients (Johnson, Leventhal, & Dabbs, 1971). If they were firstborns, internals also had longer hospital stays than externals. Johnson et al. explained the interaction between I-E and birth order as follows: They postulated that firstborns who are exposed to stress become frightened and dependent and so they try to remain in contact with the authorities who control danger. Internal firstborns have learned to manipulate the health personnel in order to remain in the hospital. External firstborns do not have sufficient skill to influence postoperative stay. Since later born patients are less dependent and frightened, they feel no need to stay longer regardless of I-E beliefs.

In another rather complicated research design, Auerbach, Kendall, Cuttler, and Levitt (1976) found no relationship between I-E scores and anxiety about impending dental procedures among a group of patients scheduled for surgical removal of a tooth. However, they did find that internal and external patients responded differentially to specific and general presurgery information. According to dentist ratings, internals adjusted poorly in surgery after receiving general, marginally relevant material about the dental procedure. However, internals showed good adjustment in surgery after viewing a tape that imparted specific information about the procedures and sensations that they might expect; the reverse was true for external patients. These investigators suggested

that internals responded favorably to the specific information, since it provided relevant input consistent with their cognitive set that they exert control of the occurrence of reinforcers and punishments provided them. The authors hypothesized that the specific information provided data that enhanced the internal's perception that he/she might manipulate the impending aversive situation, whereas the general information reinforced the ambiguity of the situation and a lack of personal control over it. They suggested that for externals, the specific information led to a diminished reliance on outside sources as the precipitating events leading to this aversive situation. The general tape allowed the external patient to avoid personal responsibility, an action congruent with a defensive posture about control of reinforcement.

In one of the most complex and well-controlled studies of personality characteristics in relation to stress, heart attack, and recovery, Cromwell, Butterfield, Brayfield, and Curry (1977) manipulated nursing care, participation in various activities, and information about heart attack for 229 coronary patients. Eighty medical patients with illnesses comparable in severity but without cardiovascular involvement served as controls. Dependent variables included stay in intensive care, stay in hospital, rate of alarms (heart rate changes while on unit), a number of biochemical and physiological indices, rehospitalization, and death. Overall, in regard to I-E scores as assessed by the Rotter scale, coronary patients were more external than the medical controls. No patients who were involved in congruent combinations of locus of control beliefs and participation in self-treatment (internals with high participation and externals with low participation) returned to the hospital ($p < .06$) or died ($p < .06$) within 12 weeks following their hospital stay. The small number of patients who did return to the hospital ($n = 12$) or who died ($n = 5$) had all been involved in incongruent conditions. As indicated by the .06 significance levels, these findings cannot be accepted with great confidence. However, the findings are in the predicted direction, and the small number of cases could have been contributed to the lack of statistical

significance. Since these are long-term effects, Cromwell et al. suggested that patients whose hospital treatment was incongruent with personal expectancies may have resisted a decision to return to the hospital when crucial symptoms of another myocardial infarction appeared. I-E beliefs were also related to a number of other dependent variables. Except in two cases in which internality was linked with high anxiety, externality was always associated with undesirable physical characteristics such as higher temperature and higher sedimentation rates. Also, internal patients were more cooperative in response to treatment demands, and they left the coronary unit and the hospital earlier than external patients. It should be noted, however, that Marston (1969) found no relationship between I-E beliefs and compliance behavior among a group of coronary patients and, with 58 male patients, Garrity (1973) found that subjects' perceptions of health status, social class, and a belief in external control predicted return to work after their first myocardial infarction.

Aside from the Cromwell et al. (1977) study, very little research is available linking I-E beliefs to specific physical illnesses. However, Naditch (1974) considered data on over 400 black men and women (in six American cities) who were diagnosed as having essential hypertension—a "silent" health hazard for large numbers of black people. Among externals who rated themselves as discontented with their lives, the rate of hypertension was 46%, more than double the 21% rate for the total sample and considerably higher than rates for all other groupings (e.g., a 7% rate for contented internals). In further analysis, Naditch concluded that these results occurred primarily as a function of the responses of males but not of females in the sample. Similar to Cromwell et al., and as would be expected from the Glass (1977) research, the Naditch I-E findings have implications for cardiovascular involvement. Taken together, these studies suggest that I-E beliefs may be particularly salient for understanding the influence of belief about control on physiologically adaptive responses to stress within the cardiovascular system. (See Strickland, in press,

for a more complete review of I-E and cardiovascular functioning.)

Darrow (1973) tested several hundred persons who presented themselves to community health centers for diagnosis and treatment of venereal disease. He found men assessed as internal to be significantly less likely to be infected with gonorrhea. No such results emerged from females, although internal women were more likely to return for follow-up treatment with the appearance of new symptoms than were external females. Darrow interpreted this latter finding as most likely being due to the tendencies of these women to notice physiological changes and to seek an explanation for the reoccurrence of symptoms after treatment. Olbrisch (1975) also reported a complex relationship between externality and naive beliefs about gonorrhea, in that external subjects appear to have a more casual, helpless attitude about how venereal diseases are contracted. In this study, however, externals did not differ from internals in plans to make further precautions.

Any impending or disabling disorder, whether chronic or temporary, has a varying degree of influence on the responses of the persons faced with the handicap. The severity of the disorder, the time of onset, the current status of the patient, the support that he/she receives, and so on, all interact with what is probably a complex set of cognitions about the disorder. When an individual is more helpless than he/she once was, or is handicapped in relation to others, beliefs about locus of control would be expected to be, and apparently are, related to reactions to the disorder and the struggle to recover. Although chronically handicapped individuals, particularly children, appear to be more external than their control counterparts, internal adults, in spite of the fact that they may respond to disablement with initial denial and concern, appear to know more about their disorder and attempt to influence health care to a greater extent than externals. These results are most clear in those complex designs that give attention to the interactions of I-E expectancies and situational demands. For example, internals seems to be able to use specific information about their disease

and treatment, whereas externals respond to general instructions. Given the initial defensiveness and denial of internals faced with trauma, a number of questions are raised as to when internal versus external expectancies are more adaptive. It may be that a defensive stance is helpful when a person who is accustomed to considerable personal control is suddenly faced with events beyond his or her influence.

I-E and Physiological Responses

Aside from the findings of relationships of I-E expectancies and general health practices, it is of interest to note the degree to which I-E beliefs may be related to an individual's ability to monitor and change specific physiological responses. A number of investigators and health care personnel have attempted to teach individuals to improve physical functioning via the use of biofeedback, and indications of individual differences in response to this technique become particularly important. Again, a logical assumption is that persons who hold strong locus of control expectancies, whether internal or external, will have differing responses to attempts to control their own internal physical states. Internals would be expected to be sensitive to internal states, alert to biofeedback cues, and motivated to attempt self-control of bodily function.

Results of several studies do show internals to be generally superior to externals in responding to biofeedback paradigms. Internals are better able to increase and maintain electroencephalogram alpha responding (Gosling, May, Lavond, Barnes, & Carreira, 1974; Johnson & Meyer, 1974) and to lower galvanic skin responses via biofeedback than externals (Wagner, Bourgeois, Levenson, & Denton, 1974). Other biofeedback research also demonstrates the influence of I-E expectancies on the control of vascular responses. Ray (1974) found internals to be more proficient at increasing heart rate and externals at decreasing heart rate than comparison subjects. These results were essentially replicated by Gatchel (1975) for the first training trial of a biofeedback paradigm. Fotopoulous (1971) reported internal sub-

jects to be more capable of increasing heart rate without either reinforcement or external feedback, whereas externals could increase heart rate only under a reinforcement paradigm.

Like the clinical findings on I-E/cardiovascular relationships, these data on the voluntary control of heart rate suggest that internals and externals may be using different strategies in biofeedback paradigms and that effective responding might be enhanced if individuals are in conditions that are congruent with their expectancies for control. As noted by Cromwell et al. (1977), internals may respond to opportunities to work individually, and externals may need conditions of structure or outside influence to enhance their responding. At least one laboratory study suggested that this is indeed the case. DeGood (1975) studied 24 internal and 24 external subjects under one of two aversive shock avoidance procedures. Half of the subjects could escape shock by asking for a rest period, and half had rest periods imposed by the experimenter. Control over initiation of rest had an arousal-reducing effect on systolic blood pressure for all subjects. Diastolic blood pressure change appeared to be a function of an interaction of I-E expectancies and the situation. Elevations were lowest when personal and situational control factors were congruent, that is, for internals in conditions of self-initiation of rest and for externals under imposed rest.

In a particularly complex biofeedback design, Carlson (in press) studied 24 male and 24 female college students who equally represented three distinct ethnic groups: Caucasians, Japanese, and Chinese. The feedback subjects acquired lower frontal electromyographic (EMG) levels than control subjects, and internal subjects in the feedback condition acquired lower levels than externals. No consistent differences in EMG levels were obtained in the control condition as a function of I-E (as assessed by the Nowicki-Strickland I-E scale for adults; Nowicki & Strickland, 1973). These results were stable across both sexes, all three ethnic groups, and across two replications. On pretest and posttest, Carlson found that external subjects in the feedback conditions shifted significantly

toward internality, suggesting that the experiencing of the opportunity for changing bodily states was related to an enhanced internal expectancy. No change scores occurred for the internal subjects, possibly because of a ceiling effect. Internal subjects in the control conditions did shift toward externality, but this change was not statistically significant. Additionally, I-E shifts were apparently not related to actual performance changes. Despite the fact that internals in the feedback condition achieved the lowest frontal EMG levels, they also reported feeling somewhat less relaxed during training than their counterparts in the control condition and the externals in the feedback conditions. Carlson suggested that in their efforts to perform well in a frontal muscle relaxation task, internals may actually sacrifice their subjective state of general relaxation. Again, these findings are reminiscent of the cardiovascular results in which internals appear to deny arousal while actually experiencing distress in situations in which they have no control.

Berggren, Ohman, and Fredrikson (1977) shed some additional light on the possible mechanisms that lead to the differential physiological responses of internals and externals to stimulus conditions. When college students with extreme I-E scores were asked to respond to a recurring tone of moderate intensity, external subjects took significantly longer to reach a criterion of habituation than internals on a measure of skin conductance. Evidently, externals were exhibiting continued electrodermal orienting responses to nonsignal stimuli. The investigators then ran additional subjects in the same methodological procedure plus a second experimental manipulation—The stimulus was given more significance by arranging that it would be a signal for a forthcoming task. Some groups of subjects were asked to press a switch at the *offset* of a recurring tone, and other groups repeated Experiment 1. Again, externals took significantly longer to reach criterion of habituation than did internals. In the signal condition, however, this effect was reversed so that internals habituated more slowly. The external group failed to differentiate between signal and nonsignal conditions. The investigators interpreted these results to suggest that

externals have poorer control of attention than internals. External subjects attended to irrelevant events and did not seem to differentiate between relevant and irrelevant cues. Internals, on the other hand, differentiated sharply between cues and stopped responding to irrelevant cues quickly. Overall, as theoretically expected, internals appeared to be vigilant, with more active attentional processes and more focus on task-relevant cues.

Physiological responding in biofeedback designs appears to be functionally related to I-E expectancies and enhanced in congruent conditions. It is likely that these effects occur because internals and externals attend and respond to relevant stimuli in different ways. Internals appear to be more motivated to succeed and are generally superior in performance than externals. However, their vigilance and attempts to control their bodily states may result in immediate increased arousal and diminished future well-being. Again, it is important to know when internals should be encouraged to relax and/or to relinquish control for enhanced physical functioning. These investigations could have direct and practical implications for preventive health practices, especially in regard to cardiovascular disease. Both internals and externals can learn to control heart rate. However, they use different strategies to do so, and their efforts may lead to different long-term outcomes. More specific investigations are needed, but evidently cognitive mediating variables about perceived control are impactful in relation to basic cardiovascular functioning.

I-E and Psychological Disturbances

Research on the I-E variable and the reporting of psychological and/or emotional difficulties is much more extensive than that on I-E and physical disorders. At a general level of overall functioning, internal individuals including the elderly (Felton & Kahana, 1974; Wolk & Kurtz, 1975) are significantly more likely to report themselves as content with their life situations than externals (Naditch, Gargan, & Michael, 1975; Palmore & Luikart, 1972). The relationships among I-E and adjustive behavior and attitudes, however, is moderated by the nature of the set-

tings in which people reside (Wolk, 1976). With regard to dysfunctional difficulties, investigators have found a belief in external locus of control to be related to debilitating anxiety (Butterfield, 1964; Feather, 1967; Finch & Nelson, 1974; Platt & Eisenman, 1968; Shriberg, 1974; Strassberg, 1973; Watson, 1967), to the holding of irrational values (MacDonald & Games, 1972), to mood disturbances (Kilpatrick, Dubin, & Marcotte, 1974), and to indices of maladjustment on paper-and-pencil questionnaires (Duke & Nowicki, 1973; Hersch & Scheibe, 1967; Powell & Vega, 1972). With patients who have been hospitalized for psychiatric reasons, a number of researchers have reported a relationship between externality and severity of psychiatric diagnosis (Cash & Stack, 1973; Croft, Johnson, & Fox, 1975; Cromwell, Rosenthal, Shakow, & Zahn, 1968; Duke & Mullins, 1973; Harrow & Ferrante, 1969; Lefcourt, 1976; Levenson, 1973; Lottman & DeWolfe, 1972; Palmer, 1971; Shybut, 1968; C. E. Smith, Pryer, & Distefano, 1971). These data are correlative, and there is no way of knowing if external beliefs accompany a predisposition to psychological difficulties or if locus of control beliefs occur as a function of the disturbances. At the least, it appears that the reporting of life contentment is related to internality, whereas pathological difficulties are linked to external expectancies.

A puzzling issue throughout a consideration of I-E and maladaptive behavior, however, concerns the discrepant predictions about externality and depression. One might logically expect that individuals who believe that they are responsible for the results of their behavior would be more likely to become depressed when life events do not go well for them than persons who are able to attribute traumatic events to luck, fate, God's judgment, and so forth. Indeed, Phares (1972) has hypothesized that "depressions tend to be associated with people who possess a strong generalized expectancy that outcomes are their own responsibility" (p. 466). The guilt and self-punitiveness often expressed by depressives would be expected to occur only if individuals actually believe that they influence life occurrences. On the other hand, many depressives report themselves to be powerless

about life events, to experience loss of control, and to feel helpless about influencing future events—all perceptions that sound similar to externality. Strickland (Note 1) and Lefcourt (1976) have both hypothesized a relationship between depression and externality, and much of the empirical literature supports this contention (S. I. Abramowitz, 1969; Calhoun, Cheney, & Dawes, 1974; Dinardo, 1972; Emmelkamp & Cohen-Kettenis, 1975; Goss & Morosko, 1970; Moyal, 1977; Naditch et al., 1975; Prociuk, Breen, & Lusier, 1976; Wareheim & Foulds, 1971; Haley & Strickland, Note 5). Considerable evidence has also accumulated with regard to I-E beliefs in relation to "learned helplessness"—a phenomenon proposed by Seligman (Abramson, Seligman, & Teasdale, 1978; Seligman, 1974, 1975) as a model for reactive depression. Generally, researchers find that externals show poorer performance in the learned helplessness paradigm than do internals (Cohen, Rothbart, & Phillips, 1976; Hiroto, 1974). Although, in at least one instance, individuals responded to helplessness manipulations with increased attempts at control (Roth & Bootzin, 1974). In fact, Brehm's reactance theory (Brehm, 1966, 1972) would predict that a person threatened with loss of freedom will become motivationally aroused to prevent their loss. Obviously, individuals have differing coping styles and respond to circumstances in diverse but possibly predictable ways. Increased research with the I-E variable might give additional clues as to individual responses to aversive or traumatic life situations. Research in this area must remain completely open, however, without presupposed judgments of what is "good" or "adaptive." As Wortman and Brehm (1975) caution, an emphasis on personal causation may be dangerous when individuals are faced with situations that are truly uncontrollable. Additional complications in this kind of research have to do with the difficulty of defining depressive responses. Depression is a multidimensional disorder, and facets of depression (e.g., reactive vs. chronic depression) may be differentially related to I-E. In fact, Strickland and Hale (Note 6) found external expectancies to be more strongly related to a measure of chronic depression than to temporary depressed mood.

Further, when factors or dimensions within the I-E construct are examined, they lead to differential predictions. For example, depressives take responsibility for negative but not positive events in their lives (Haley & Strickland, Note 5). Clearly, the relationships are complicated and further research is necessary. The I-E variable would appear to be particularly useful in relation to cognitive theories of depression (Beck, 1976) and in models incorporating response-contingent hypotheses (Lewinsohn, 1972). Of particular importance are those critical studies linking cognitive variables to overt behavior.

Even though depression takes its toll in lessened feelings of well-being and happiness as well as in loss of energy, perhaps the most serious aspect of depression is the possibility of suicide that occurs for many depressed individuals. Several investigators have considered the relationships among suicidal thought, behavior, and I-E expectancies in an attempt to better understand life-threatening behaviors. Lambley and Silbowitz (1973) could not predict the contemplation of suicide via Rotter's scale, but Williams and Nickels (1969), in a study of 235 college students, found externality to be related to suicide potential as measured by the Minnesota Multiphasic Personality Inventory. Crepeau (Note 7) also asked college students how often they contemplated suicide. Generally, he found suicide ideation to be linearly related to Collins' (1974) I-E measure, with persons who reported suicidal thoughts being assessed as more external than students who had never considered suicide.

Melges and Weisz (1971) talked with 15 patients who had recently made serious suicide attempts. They asked them to recall as vividly as possible the feelings and thoughts that they were experiencing immediately before the attempt. With pretest and posttest measures, they found increased externality following the specific suicide ideation. Patients also reported more negative evaluations of the future and less extension of a span of awareness toward the future. Both of these variables were also related to changes toward externality. Thus, findings from reports of the reexperiencing of suicidal thoughts suggest that the original suicidal impulses may

reflect a feeling of loss of control and an inability to foresee a pleasant future.

Although many of the empirical results reported in psychological literature point to a relationship between beliefs about external control and psychopathology, this finding does not hold in some selected samples of maladaptively functioning persons. For example, considerable confusion is apparent in studies with individuals who are substance abusers. Some investigators reported alcoholics to be more external than control samples (Butts & Chotlos, 1973; Naditch, 1975; Nowicki & Hopper, 1974; Obitz & Swanson, 1976; Palmer, 1971), and others found alcoholics to be more internal (Goss & Morosco, 1970; Oziel, Obitz, & Keyson, 1972). Caster and Parsons (1977) found that alcoholics score higher than control subjects on the Chance Control dimension of Levenson's scale and noted that treatment success varied in relation to I-E scores. A correlation between external Control by Powerful Others and depression was evident in successfully treated groups, whereas a relationship between depression and Chance Control was found for failures. Caster and Parsons suggested that alcoholics who are depressed and who see their distress as occurring because of powerful others may respond better than those alcoholics for whom depression is psychologically related to fate or chance. Other investigators have suggested that I-E differentiates among alcoholics, with those holding internal expectancies being less severely disturbed. Internal alcoholics also experience a greater magnitude of control over intrapersonal and interpersonal stresses than the external alcoholics (Donavan & O'Leary, 1975; Donovan, O'Leary, & Schau, 1975; O'Leary, Donovan, & Hague, 1974a, 1974b; Pryer & Distefano, 1977). Although one might theoretically expect drug abusers to be external, some investigators reported them to be more internal than control groups (Berzins & Ross, 1973; Calicchia, 1974; Smithyman, Plant, & Southern, 1974). Again, a number of factors may be operating here, with complications arising because of the complexities of the disorders, difficulties in diagnosis, and the impact of situational demands in the testing sessions. Rotter (1975) noted that alcohol and drug abusers may be responding to the

exhortations of staff members in treatment programs who tell patients that the success of treatment is "up to them." They may dissimulate on I-E measures to present themselves in a favorable light. Although Rotter (1966) attempted to control for social desirability in the early I-E assessment instruments, a number of investigators have reported a relationship between internality and socially desirable responses (Cone, 1971; Harris, 1975; Hjelle, 1971; Vuchinich & Bass, 1974). Thus, some of the reported relationships between externality and the reporting of psychopathological symptoms may be a function of approval-motivated response set rather than veridical representation of locus of control expectancies.

I-E and Psychological Treatment

Assuming for the moment, however, that externality and maladaptive functioning are related raises a number of questions about responses to psychotherapy or treatment programs in relation to I-E expectancies. Conceptually, internals might enter therapy or treatment at a less disturbed level than externals. Once in treatment, internals would be expected to respond in adaptive ways, assuming responsibility for their difficulties and attempting to change. This assumption, of course, depends on the therapeutic approach (Nowicki, Bonner, & Feather, 1972). Internals might be quite resistant to interventions that they perceive as limiting their freedom or control. And, as mentioned earlier, therapeutic benefits might be most enhanced when individuals are in treatment situations congruent with their locus of control beliefs.

Generally, results of a large number of studies across different treatment modalities suggest that individuals in therapy or self-improvement groups do become more internal as treatment progresses (Diamond & Shapiro, 1973; Dua, 1970; Eitzen, 1974; Gillis & Jessor, 1970; Lewis, Dawes, & Cheney, 1974; Kilmann & Howell, 1974; Lynch, Ogg, & Christensen, 1975; Pierce, Schauble, & Farakas, 1970; Schallow, 1975; R. E. Smith, 1970). Academic underachievers also appear to become more internal in response to counseling and structured group activities (Fel-

ton & Biggs, 1972, 1973; Felton & Davidson, 1973; Felton & Thomas, 1972; Nowicki & Barnes, 1973; Reimanis, 1974), as do juvenile felons (Moser, 1975).

Several more studies demonstrate the more complicated interactive effects when subjects are differentiated according to I-E expectancies and placed in varied treatments (Abramowitz, Abramowitz, Roback, & Jackson, 1974; Friedman & Dies, 1974; Kilmann, 1974; Kilmann, Albert, & Sotile, 1975; Morley & Watkins, 1974). Generally, if given an opportunity, internals report that they prefer more client control than do externals. Internals respond more positively to nondirective approaches in which therapist intervention is minimal and structure is not imposed from the outside. Externals, on the other hand, appear more positively influenced by structured approaches. These findings parallel those behavior modification results that occur when individuals are differentiated as to I-E expectancies and exposed to different procedures (Best, 1975; Wallston, Wallston, Kaplan, & Maides, 1976). For example, Best and Steffy (1975) involved internals and externals in one of two smoking modification procedures. Congruence of I-E expectancies and experimental conditions produced the most profound changes. Internals responded to an aversion satiation procedure, and externals responded to an agent who decided the rate at which smoking would be reduced.

Aside from responses of clients or patients, several investigators have assessed I-E expectancies of mental health personnel and have suggested that locus of control beliefs may be important in determining the efficacy of mental health care delivery. Beckman (1972) found volunteers in a state mental hospital to be more internal than undergraduate controls and to be less likely to believe that patients should be restricted in their social functioning. Felton (1973) reported mental health workers to be more internal as a function of a process-oriented training program. Martin and Shepel (1974) trained 21 senior female nurses from urban hospitals in counseling, emphasizing developing a helping relationship, identifying and exploring problem areas, and devising plans of action. Through pretesting and posttesting, they

found both an increase in counseling perceptiveness and a shift toward internality. A correlation of .56 was found between counseling skills and internality at the posttesting.

Overall, the reported research for both individuals in treatment programs and individuals delivering mental health care suggests that internal expectancies may facilitate responsible adaptive responses. Results appear to be highly influenced, however, by the conditions under which counseling or treatment occurs. Again, congruence between locus of control expectancies and the structure of the therapeutic endeavor appears to lead to the most pervasive changes.

Problems

The increase in research on I-E expectancies and health-related behaviors is quite striking since the first Seeman and Evans study in 1962. The blending of interest in individual difference variables and health most likely results from an increased focus on preventive health care in this country and a changing social and political awareness in which individual responsibility for one's own health is emphasized. Certainly, a number of health practitioners have noted that many of the psychological and physical disorders that persons bring into a physician's or counselor's office result from, or are exacerbated by, behavior such as smoking, improper diet, lack of exercise, and substance abuse. Others have remarked on the striking individual differences in response to treatment programs once problems or physical dysfunctions are identified. Finally, increasing health costs have caused massive concern on the part of individuals who can no longer afford health care and the politicians who represent them. Overall, research with the I-E dimension suggests that beliefs about locus of control of reinforcement are influential in relation to health.

Some major problems with this research should be noted, however. First, much research that does not produce clear-cut or substantial results is not published. Implications of the published results are important, but these would, of course, be attenuated if they reflected only a small part of the work that has been done but not published.

A second major problem has to do with the relative magnitude of the I-E/health relationships that are reported. The I-E variable is only one of a number of complex factors that may converge to predict health attitudes and behaviors. The amount of variance for which I-E accounts is probably quite small in many, if not most, situations. For example, whether persons present themselves to a physician's office for relief of symptoms may be much more a function of severity of symptoms, the individual's financial condition, and/or the availability of health care than the person's beliefs about control of reinforcement. Thus, practical prediction and clinical intervention must be continually accompanied by further investigation of the complex of components that accompany health behaviors.

One of the most pervasive problems of research with the I-E dimension has to do with the differing definitions that have been attached to this construct and the fact that I-E expectancies are often, even usually, explored outside the theoretical net in which this concept was first described. Investigations using the I-E variable have proliferated, sometimes without a clear grounding in a precise understanding of the construct and its implications. Rotter (1966, 1975) has always noted that I-E is only one of a number of variables that would be expected to predict behavior in specific and novel situations. An equal concern with the nature of the situational demands and reinforcement value should improve prediction.

Aside from theoretical concerns, a number of methodological weaknesses are apparent in much of the I-E/health research. Particularly with the use of clinical populations, controls are often lacking with respect to severity and length of disorder or illness. Also, treatment methods vary when disorders are identified. Moreover, much of the research is correlational in nature and gives no indication of direction of causality. The findings that do emerge demand further investigation as to their continued viability and validity, with particular emphasis on antecedent conditions.

Another major methodological problem has to do with the measurement of I-E expectancies. Numerous I-E assessment instruments are currently being used. Most of the

research surveyed in the present article, unless otherwise noted, has been conducted with the Rotter scale, which has been the instrument in most frequent use. However, I-E measures different from the Rotter scale were sometimes used, particularly in the very earliest and the latest studies. The conflicting I-E/health findings that emerge might then be explained as occurring because of the use of the different assessment instruments that may not be measuring the same expectancies. Moreover, some I-E assessment devices are more appropriate for and better predictors of health concerns than others. The scale developed by the Wallstons, for instance, is specific to health and would be expected to enhance prediction of health-related behaviors.

Finally, the problem of response set is always one that haunts any self-report measure. This is especially telling for the I-E dimension, since significant correlations between the various I-E measures and social desirability responding are often reported. It is difficult to know the degree to which I-E responses reflect veridical descriptions of locus of control beliefs or are colored by the respondent's attempt to present himself/herself in a favorable light. Particularly in situations with strong social demand characteristics, such as treatment programs for incarcerated substance abusers in which responses may influence length of stay in institutions, individuals may be expected to respond in ways that are designed to please the controlling agents. Even within a more typical outpatient situation, persons may wish to present themselves favorably to the authorities and therapists responsible for their care, implying that they are motivated, concerned, conscientious, and so forth. Also, response bias may occur on the various I-E measures as a function of respondents' social-cultural background (Nowicki & Strickland, 1973), race (Gurin et al., 1969), sex (Strickland & Haley, Note 8), and political ideology (MacDonald, 1972). More accurate assessment of the degree and specificity of I-E expectancies, independent of mediator variables and response bias, if possible, would be enormously helpful.

In spite of the problems, research on the I-E dimension in relation to health appears to have opened significant avenues of investi-

gation that should be pursued. Although results are not altogether as clear, convincing, and as free of conflict as one might hope, the bulk of the research is consistent in implying that when faced with health problems, internal individuals do appear to engage in more generally adaptive responses than do externals. These range from engagement in preventive and precautionary health measures through appropriate remedial strategies when disease or disorder occurs. Findings suggest that the development of an internal orientation could lead to improved health practices for some individuals who have been inclined to believe that life events are beyond their responsibility and more a function of external control. One must be quite cautious, however, in assuming that internal beliefs are always facilitative. The continued alertness of internals and their attempts at mastery behavior is most appropriate when events are actually controllable. When individuals persist in efforts that bring no relief, then they may find themselves to be actually exacerbating the undesirable characteristics of the situation in which they find themselves. Perhaps the wisest course is that people learn to specify the reality of their life situations, their possible responses, and the potentiality of forthcoming reinforcement.

Another major finding emerging from this review is that congruence of expectancies and situations appears to enhance behavior change. Practical implications are that change agents such as health personnel will be most effective when techniques are tailored to individual expectancies. External individuals evidently respond more easily to conditions in which structure is imposed from outside. Internals prefer situations in which they can assume responsibility and work independently.

Obviously, continued research is necessary. The problems extant in the investigations under review are myriad, but the already observed results hold promise for both theoretical and practical advances.

Multivariate Classification of Day-Care Patients: Personality as a Dimensional Continuum

Rudie J. Lang

Institute of Psychiatry, University of London
London, England

The categorical versus dimensional view of psychiatric abnormality was examined for three groups of dysthymic neurotics, schizophrenics, and alcoholics. A discriminant function analysis correctly assigned 70% of the patients to their a priori diagnostic profiles, though the "hit rate" rose to 90% when patients were aligned on a continuum of severity in two-dimensional person space. Univariate F ratios showed the three phenotypes to differ on 12 of 26 parameters, yet 18 significant F s emerged when the patients' degree of neuroticism was taken as a putative index of general maladjustment. Results showed that Eysenck's Extraversion and Neuroticism personality factors share a considerable degree of collinearity with the factorially pure Tryon-Stein-Chu trait clusters. Many forms of psychopathology, it is argued, simply reflect gross deviations of the continuously variable dimensions of personality, not discontinuities with qualitative change points. Given a broader context, a "dimensional" model of personality functioning may well, owing to its theoretical quantifiability, supercede the notion of psychiatric "disease" types.

For over 25 years, and perhaps a half-century, the controversy between advocates of the medical model in present-day psychiatry (Panzetta, 1974; Robins, 1976) and its critics, those who prefer to advocate a dimensional system (Eysenck, 1970; Eysenck & Eysenck, 1976; Kendall, 1968; Sjöbring, 1974) has steadily gained momentum. The "dimensional" approach, favored by psychologists, repudiates the notion that functional disorders exist as qualitatively distinct entities, much in the sense that in-

fectious diseases do in *re naturae*. As such, psychiatric theory leads to the practice of viewing a problem as conspicuously present or absent, that is, to labeling a patient either as a hysteric (Briquet's syndrome) or as something else. The underlying assumption on which such terminology and its application rests, inextricably linked to general medicine, is not only of doubtful value but has led to many polemical attacks on the alleged usefulness of the "medical" model in the study and treatment of psychologic morbidity (Eysenck, 1973).

This study was in part based on a Master's of Science thesis submitted by the author to the University of Calgary, Canada.

The valuable support and direction provided by the committee chairman Barry Frost is gratefully acknowledged. Appreciation is also extended to Philip Eaton, Jan Thurgood, and the other staff of the Holy Cross Hospital for their cooperation and support of this research project. However, the views expressed in this article can be attributed solely to the author.

Requests for reprints should be sent to Rudie J. Lang, Institute of Psychiatry, University of London, De Crespigny Park, Denmark Hill, London, SE5 8EA, England.

Instead, the "dimensionalists" claim that a more sensible course to follow is to depict any given debilitating trait (or symptom) on a variable severity continuum, from normal to grossly abnormal. In its simplest terms, this allows the clinician to portray each person according to their infinitely graded *degree* of observable behavior. Obviously, some people, usually in response to real problems and pressures will, at times, appear less their usual extraverted self as they display increasing signs of social isolation, regress from a confident mood to one

of tension or worry, or experience an abrupt cognitive shift from lucid perceptivity to exhibit bizarre delusions of guilt, power, or inferiority. These deviations signal a disruption of the normal continuity of the personality. Any sudden change of emotion, attention, arousal, or perception reflects but one of many intermediate variations on a continuum between healthy and psychiatrically ill states, rather than a clear-cut separation between the two. By analogy, a patient's mental or behavioral state can be portrayed in a manner directly akin to how IQ scores are distributed in the population continuum, fluctuating from severe mental handicap to creative genius.

Briefly, dimensional analysis is based on a number of orthogonal (or independent) personality traits that serve as reference axes, normally distributed and genetically based. Each person is represented by one or more diagnostic points in n -dimensional space, relative to other patients' points. No arbitrary cutoff rules are imposed on the patients' positional loci in multidimensional space. Nor is the dimensional model hampered by the presence of "mixed" or "undiagnosed" psychopathology. Other than pure diagnostic types, the majority of patients will be uniquely placed relative to one or more dimensional reference factors, enabling a reliable probability estimate to be made of the degree to which neurotic or psychotic personality traits are causing the disturbed behavior seen in the patient. It is widely known that in the multivariate domain, *person* space and *variable* space do not correspond to the medical disease entity as it exists in psychiatric theory. As standardization data are accumulated, with broad generalizability, as was assiduously collected for norming intelligence tests, a patient's dimensional profile can guide clinical assessment, choice of treatment modality, and need for community follow-up.

Notably, the major criterion of any disease entity, apart from etiology, course, and outcome, must be one of empirical—not theoretical—discontinuity between nosological types (Kendall, 1975). This, of necessity, implies *mutual exclusivity*.¹ Not only personality disorders, but many other diagnostic

subtypes are "notoriously unreliable categories"; and reviews of studies under optimal conditions of diagnosis (Spitzer & Fleiss, 1974; Walton & Presly, 1973) clearly support this proviso. Similarly, an extensive United Kingdom-United States cross-cultural study has shown that American psychiatrists overdiagnose schizophrenia and underdiagnose affective disorders (Cooper, Kendall, Gurland, Sharpe, & Copeland, 1972). Particularly noteworthy is the lack of satisfactory agreement among clinicians, inconsistent use of terminology, and inherent gaps in the nomenclature itself, further compounded by the indecision whether to rate a trait as pathologic or as a normal variation (Presly & Walton, 1973).

For the present, at least, the psychiatric classification scheme and its newly proposed Diagnostic and Statistical Manual of Mental Disorders (DSM-III), though based on a multiaxial system, is not in a form that permits empirical testing by suitable experiments. Potentially, as every science progresses from descriptive, symptom-based classification to a dimensional framework (Hempel, 1967), the real issue may be more of a question of within what dimensionality the "symptom sign" patterns, or personality traits, lie. Like cognitive abilities, the processes underlying arousal and clinical abnor-

¹ If we single out phenylketonuria and color blindness, they reflect but two mutually exclusive kinds of biological abnormality, each occupying a discrete factor space. Yet both of these disease entities can occupy the same person space in cases in which they co-occur in the same individual. Anxiety and depression, two intermediate conditions often viewed as phenomenologically distinct, not only share the same person space (e.g., as when a patient displays both), but they frequently load on the same factor across studies, confirming their factorial interdependency (Lang & Frost, Note 1). Unlike infectious diseases, surprisingly few of which truly exhibit uniquely identifiable causes, behavioral or personality traits often share a multiple, or overlapping, etiology and, in this sense, cannot be adequately defined by the arbitrary cutoffs imposed by a medically based, nosological psychiatric system. Many other common illnesses such as diabetes mellitus, rubella, peptic ulcer, and coronary heart disease can now be more readily investigated in dimensional than in categorical terms.

malities are often discovered to be complex and continuous rather than discrete. In this sense, they are more likely to be *hierarchically organized within dimensions* and less likely to exist in some either/or paradigm as predicted by psychiatric theory. The typologic model tends to confuse the predisposition with the neuroses and psychoses while ignoring the underlying continuum of mental disturbance.

Since little is actually known about the underlying distribution of clinical pathology in the general population continuum, or about those subclinically predisposed to develop mental conditions, a major task is to specify, as a probability estimate, the likelihood that a person will become behaviorally disturbed. The risk factor will vary and can, in dimensional terms, be expressed as a probability function, such as in the "diathesis model of stress" proposed by Edwards (1969).

Unquestionably, the eventual resolution of the continuum-category debate has major ramifications for the prophylaxis and treatment of the deviant personality and direction dictated to future research trends. If the advent of a "dimensional scientology" is already underway—and not 300 years ahead as Robins (1976) intimates—it must stand or fall on its own merits. In fact, there is good reason to believe that people vary enormously in their predisposition to become stressed, whether genetically or environmentally induced. Physically, anyone can potentially break a leg (i.e., qualitative), yet the person with weak fibrous tissue is much more susceptible to accidental injury (i.e., quantitative). As such distinctions are measurable, a coordinate dimensional view of personality would provide valuable data to assess, in probability terms, the degree to which a referred patient is genetically or socially predisposed to overreact to daily stressors. The dimensional model, owing to its theoretical quantifiability, is obviously superior, as it can be tested empirically.

The continued use of qualitative change points, arbitrarily applied, ensures the kind of diagnostic unreliability that is commonly found. By definition, such points remain undefinable. Perhaps, as Wing (1976) re-

marked: "Some combination of the two . . . may eventually allow clinician and scientist to make the best of both worlds" (p. 394). There is, demonstrably, a considerable degree of collinearity between the dimensional personality model and the psychiatric disease system (Eysenck & Eysenck, 1976) to make this transition possible.

Given some of these empirical and theoretical issues, the main purpose of the study is addressed to three questions. First of all, a discriminant function analysis examined the extent of agreement between psychiatrically assigned diagnoses and computer-generated diagnoses for different subsets of clinical predictor scales. A second purpose was to contrast the categorical-dimensional approaches by taking the dimensionally complex Neuroticism factor as a putative index of severity (or level) of maladjustment to the exclusion of the patients' designated diagnostic codes. The third aim was to check the degree of "collinearity" between two of Eysenck's major personality dimensions, namely, Neuroticism and Extraversion, and behavior as measured by the factorially pure Tryon-Stein-Chu "sign symptom" clusters, derived from the standard Minnesota Multiphasic Personality Inventory (MMPI) item pool. Recent evidence by Wakefield, Yam, Bradley, Doughtie, and Cox (1974) suggests that the Eysenck Personality Inventory and MMPI converge in multivariate space, even though the two instruments represent separate approaches to personality assessment. Much like Eysenck, Royce (1973) pointed out that the many primary factors can be adequately accounted for by three major "superfactors," which Royce calls anxiety, introversion, and superego. As a subsidiary hypothesis, it was expected that the *real* differences in morbidity reside not in the erroneous reliance on a diagnostic label but inherently exist within the configurations of disturbed patients at each symptom level, and presumably of how their scores on critical traits *covary* together.

Method

Subjects

One hundred fifty-seven outpatients recently admitted to the Holy Cross Hospital, Day Care Treat-

ment Centre, located at Calgary, Canada, served as subjects. Fifty-four were male; 103 were female. The mean age of the total group was 37.84 years ($SD = 11.83$ years).

Upon initial admission to the hospital, every patient was first seen by the duty doctor in the emergency clinic and was then interviewed by a senior consultant psychiatrist, who assigned patients to the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-II; American Psychiatric Association, 1968). The classifications were 86—neurotic depression (300.4), 38—alcoholic abuse (303.0), and 33—paranoid schizophrenic (295.3). Clearly, it would have been desirable to have two resident psychiatrists separately assign the working diagnoses, enabling a measure of interrater reliability to be computed. Even so, under optimal conditions with two or more raters, "there are no diagnostic categories for which reliability is uniformly high" (Spitzer & Fleiss, 1974, p. 344). In dealing with such patients, the continued usage of qualitative terms to designate arbitrary cutoff points along a dimensions ensures, almost certainly, the kind of poor reliability that besets psychiatry as a whole. Thus, for all patients who were psychiatrically diagnosed, there is always the unreliability of such diagnoses to contend with. I am well aware of the unreliability of making such diagnostic judgments; however, common practice used in handling the vast majority of new admissions is to have one senior staff psychiatrist assign a differential diagnosis. Therefore, it is quite reasonable to contrast its usefulness against that of the dimensional approach. This article will attempt to clarify this point by showing that the dimensional model is empirically superior, owing to its theoretical quantifiability.

Following the preliminary intake, each patient was interviewed by the day care management team to determine their suitability for the day care program. The psychometric evaluation was carried out in small office-type rooms, usually in two sessions over a 1- to 3-day interval. Most patients were on maintenance drug therapy. The prescribed drug was usually a tricyclic antidepressant (e.g., amitriptyline hydrochloride, imipramine), an anti-anxiety drug (e.g., chlorodiazepoxide, diazepam) or a antipsychotic medication (e.g., pimozide, haloperidol, fluphenazine hydrochloride, trifluoperazine) at moderately low, rather than peak dosage levels, so as not to impair their ability to provide suitable coherent responses.

Alcoholics were detoxified for at least 10–14 days; and no patient who had undergone recent electroconvulsive therapy was tested. Thus, all patients were sufficiently reality oriented to properly understand the nature of the questionnaire forms, and they did not display a marked intellectual deficit.² Due to their deteriorated condition, certain highly disturbed or acutely ill persons, irrespective of clinical diagnosis (those psychotically depressed, in a manic phase, or otherwise badly hallucinated), were simply untestable. Thus few acutely psychotic patients were ipso facto included in the study be-

cause they, behaviorally, precluded themselves. Otherwise, the final sample, excluding these few, formed a fairly representative sampling of psychopathology from the general population continuum.

Measures

Wechsler Adult Intelligence Scale (WAIS; Wechsler, 1955). Only the WAIS Vocabulary and Block Design subtests were administered on the basis that in independent analyses of dyads of WAIS subtests, both Maxwell (1957) and Silverstein (1970b) have shown that the Vocabulary–Block Design pair is the "best" combination for computing a prorated full-length WAIS IQ.

Tennessee Self Concept Scale—Clinical and Research Form (TSCS; Fitts, 1965). The TSCS booklet is made up of 100 first-person statements to which the subject responds on a 5-point Likert-type scale, ranging from completely true to completely false. The TSCS contains 90 items that evaluate five external references of self-concept: "physical self," "moral-ethical self," "personal self," "family self," and "social self," supplemented by a 10-item Self-Criticism scale.

Eysenck Personality Inventory (Eysenck & Eysenck, 1968). Form A of this questionnaire was used; it consists of 57 yes–no questions: 24 evaluate neuroticism–emotional stability, 24 evaluate introversion–extroversion, and 9 items constitute the Lie (or "social desirability") scale.

Tryon-Stein-Chu (TSC) scales (Stein, 1968). This 200-item inventory was developed by cluster analyzing the 550 original MMPI item pool. This eliminated the contamination due to item overlap, as only the purer nonoverlap items were retained to reduce the effects of spuriously shared variance. There are eight TSC scales: Social Introversion; Body Symptoms; Suspicion and Mistrust; Depression and Apathy; Resentment and Aggression; Autism and Disruptive Thinking; Tension, Worry, and Fears; and Lying (or Dissimulation).

Nurses' Observation Scale for Inpatient Evaluation (NOSIE; Honigfeld & Klett, 1965). This rating scale contains 80 behavioral items, each of which is rated on a 5-point frequency continuum, ranging from never to always. Only five social adjustment scales were used: Social Competence, Social Interest, Personal Neatness, Cooperation, and Irritability. A team of mental health workers and psychiatric nurses rated each patient on each of these indices following no less than 7 days of careful observation in vivo.

² The mean WAIS IQ, prorated from the summed Vocabulary and Block Design scores using Silverstein's (1970a) conversion formula (age corrected for the 34- to 44-year-old group), was 103 to indicate that patients were of average intellectual ability.

Procedure

Phase 1. To begin, all patients were classified into a priori groups in conformity with their assigned psychiatric diagnoses. A stepwise discriminant function analysis was carried out to ascertain the extent of agreement between the categorical diagnoses and computer-generated profiles for three types of data variables (scores based on observational, self-report, and cognitive assessment). Three combinations of predictor scales were used: (a) all 26 independent variates; (b) the seven TSC subscales; and (c) the Extraversion and Neuroticism factors.

Phase 2. Second, all patients were divided into three clusters along a continuum of neurotic severity. Of the possible choices, Eysenck's Neuroticism was preferred as it represents a universally stable, personality factor. Thus, the 157 cases, regardless of assigned diagnoses, were positioned within a dimensional framework in keeping with their level of maladjustment, namely, Neuroticism (N) scores. The severity continuum consisted of three levels: low N scores (0-7), moderate N scores (8-13) and high N scores (14-23). In this way, it was possible to plot, or align, the patients along a graded, dimensional personality factor and then contrast this approach against the notion of a disjunctive psychiatric entity.

Statistical treatment. Initially, Pearson product-moment correlations were computed for all 26 variates in the raw data matrix. The suitability of the resultant multiple correlation matrix for further multivariate analysis was ensured by the Dzuiban and Shirkey (1974) test, which ruled out the possibility of random fluctuation. Given each subject's observed series of scores, the discriminant program computes a set of lambda weights (the larger lambda is, the less discriminating power present) that are applied to the raw scores of the data variables for each case, producing a standard score for each subject (Cooley & Lohnes, 1971). The individual test scores are then transformed into a single discriminant score, and that score is the patient's locus in n -dimensional space. For two or more groups, the number of discriminant functions is always a potential maximum of $g - 1$ functions, each of which define an orthogonal reference axis in geometric space (Nie, Bent, & Hullz, 1970).

Both the BMD (Dixon, 1972) and FORTRAN (Veldman, 1967) computer programs generate an approximate F test of significance based on Wilk's lambda to determine the equality of group covariance matrices. Lambda can be transformed into a chi-square statistic to test the significance level of each successive function. Likewise, the relative sizes of λ_i (eigenvalues) and their associated canonical correlations denote the ability of each function to maximally separate the groups.

When two discriminant functions are derived, the group centroids (means of each group on all functions) can be plotted in geometric space to give an optimal two-dimensional picture of the degree of group separation. The mathematical logic of dis-

criminant analysis assumes that the data variables are sampled from a multivariate normal distribution having equal variance-covariance matrices within groups. However, owing to the robustness of the technique, these assumptions are often not strongly adhered to. To correct for unequal N sizes, a Bayesian adjustment of the $\log |H|$ sign was made based on a priori knowledge of group membership probabilities. The prior probability values were thus set equal to the cell frequencies. The classifications are based on the separate group covariance matrices, rather than the pooled within-groups covariance (dispersion) matrix, as illustrated by Cooley and Lohnes (1971, chap. 10).

Moreover, the magnitudes of the weighting coefficients, in standardized form, are closely analogous to beta weights in multivariate regression formulas. Hence, like regression coefficients, all discriminant function coefficients change in value with the addition or deletion of a variable from the specified analysis, requiring a recomputation of the functions at each stage. The standardized function coefficients depict the relative contribution of its associated variable to that function. As in factor analysis, these coefficients are often used to "label" each function by identifying the dominant characteristic that they measure. Based on the discriminant score, cases are assigned to the diagnostic category for which the computed probability density is largest. Finally, subprogram DISCRIMINANT tests the significance of the scale means of the measures for each subgroup by univariate and step-down F values.

Results

Analysis 1: Diagnostic Criterion

Twenty-six variables. The test of overall differentiation for the three clinical typologies, Wilk's lambda (the associated chi-square of each discriminant function), and correlations of the 26 predictors are presented in Table 1. For the overall analysis, Wilk's $\Lambda = .652$, which is significant ($p < .001$). The nature of these discriminant functions can be determined by examining the large contributors to group separation. The first function is bipolar, being positively weighted by WAIS Vocabulary; and Neuroticism; Self-Criticism; Introversion; Depression; Tension, Worry, and Fears; Cooperation and Social Interest; and negatively by Extraversion; Personal Self, and the EPI Lie scale. This first function, or ordinate, contains a number of the primaries that comprise Eysenck's Neuroticism or Cattell's Anxiety superfactors.

The second variate, namely the abscissa, has its positive pole defined by Suspicion-

Table 1
Correlations of 26 Variables With Two Discriminant Functions and Tests of Significance for Three Psychiatric Subgroups

Predictor	Discriminant function			
	Diagnostic codes ^a		Symptom severity ^b

Sex gender	.22	-.33	.42	.44
% variance	58.59	41.39	74.43	25.57
Bartlett's χ^2	83.66	35.87	93.19	53.09
df	50	24	49	23
p	.002	.056	.001	.012

Note. WAIS = Wechsler Adult Intelligence Scale; EPI = Eysenck Personality Inventory; MMPI = Minnesota Multiphasic Personality Inventory.

^a Wilk's Λ = .462, $F(2, 154) = 20.90$, $p < .001$.

^b Wilk's Λ = .447, $F(2, 154) = 18.78$, $p < .001$.

Mistrust, the EPI Lie scale, Resentment-Aggression, Autistic Thinking, and the MMPI Lie scale, whereas the negative pole points to deficits in Extraversion, Personal Neatness, Social Interest, and Social Competence. Generally, then, the subset of variates that define this latter function reflect the more acute symptomology typical of the psychoticlike profile. It presumably refers to a Psychoticism dimension.

To facilitate interpretation, the group centroids are plotted in Figure 1. As is apparent, there is substantial overlap between the three typologies. They are not clearly truncated,

even though the discrimination is statistically significant. For the dysthymic neurotics, the total battery classified them with 75.6% efficiency, misclassifying 21 of these 86 patients. Table 2 shows how this ratio dropped to 60.6% agreement between diagnosis and objective tests for schizophrenics, whereas a 65.8% concordance was achieved for the alcoholic group. For the most part, the 30% misclassification rate may be due largely to the speculative nature of the defining criterion, not the standardized objective tests. That the differential diagnoses of 47 of 157 patients showed a poor fit to the clinical data

Table 2
Diagnostic Classification by Discriminant Function Analysis for Different Combinations of Predictor Equations

Measure	Actual group	Predicted group membership		
		1	2	3
26 variates ^a	Neurotics	65 (75.6)	6 (7.0)	15 (17.4)
	Schizophrenics	10 (30.3)	20 (60.6)	3 (9.1)
	Alcoholics	10 (26.3)	3 (7.9)	25 (65.8)
7 MMPI scales ^b	Neurotics	66 (76.8)	7 (8.1)	13 (15.1)
	Schizophrenics	14 (42.4)	17 (51.5)	2 (6.1)
	Alcoholics	12 (31.6)	2 (5.3)	24 (63.1)
2 EPI scales ^c	Neurotics	66 (76.8)	8 (9.3)	12 (13.9)
	Schizophrenics	13 (39.4)	15 (45.4)	5 (15.2)
	Alcoholics	11 (29.0)	4 (10.5)	23 (60.5)

Note. Numbers in parentheses are percentages. For neurotics, $n = 86$; schizophrenics, $n = 33$; alcoholics, $n = 38$. MMPI = Minnesota Multiphasic Personality Inventory; EPI = Eysenck Personality Inventory.

^a $\chi^2(4) = 134.27, p < .001$; 70.70% of cases were correctly identified.

^b $\chi^2(4) = 97.20, p < .001$; 68.15% of cases were correctly identified.

^c $\chi^2(4) = 89.77, p < .001$; 66.24% of cases were correctly identified.

is in accord with their widespread unreliability (Kendall, 1975). Moreover, the test(s) may be more valid than the criterion!

MMPI scales. The overall test of between-group differences, Wilk's lambda criterion, converted to Rao's F approximation, for the abbreviated MMPI (TSC trait clusters) is

highly significant ($p < .001$). Of seven TSC scales, five contributed significantly to group separation. According to Table 3, the two best predictors were Social Introversion and Tension, Worry, and Fears. Despite two significant roots, the discriminant analysis was only able to correctly identify 68.15% of patients as members of the consensual class that they were intended to depict (see Table 2). Classification figures for alcoholics (68.1%) and paranoid schizophrenics (51.5%) were uniformly poor but were somewhat better for dysthymic neurotics (76.8%). As the shorter MMPI (i.e., Midi-Mult) enjoys wide usage as a diagnostic tool, the substantial overlap runs contrary to the notion of a qualitatively distinct, categorical entity.

That a sizable number of patients (50 of 157) do not exhibit finite, qualitative change points in multiperson space provides, at least, a justifiable *raison d'être* for exploring the merits of a dimensional system of personality description. Here again, the absence of any marked points of "rarity" runs counter to classical theory.

EPI scales. Third, a prediction model using only a single pair, the extraversion and neuroticism personality traits, was used. Wilk's lambda for the three-group differentiation was .572, which was significant ($p <$

Figure 1. Position of 86 dysthymic neurotics, 38 alcoholics, and 33 schizophrenics on two canonical variates based on 26 discriminant scores. (Latent roots: $\lambda_1 = .461$ (58.6%), $p < .002$; $\lambda_2 = .717$ (41.4%), $p < .056$.)

.001). Two latent roots, respectively, accounted for 85.8% and 14.2% of trace. Given this dyad, the stepwise procedure allocated 66.24% of all cases to their intended conceptual categories. Indeed, this is actually only 2% fewer than the foregoing TSC scales and scarcely 4% less than the overall battery.

For this subanalysis, nearly one half of the alcoholics and about 40% of schizophrenics were erroneously assigned, much like the shorter MMPI. By way of comparison, the 2% (or three patients) higher "hit rate" of the pure TSC validity scales, over the much briefer EPI, is hardly a noteworthy advantage for an inventory directly enquiring about "signs and symptoms." Interestingly, each inventory classified 66 or 86 neurotic depressives (a difficult category). Whenever the aim is to classify patients into psychiatric clusters, certain *scalar combinations* may prove more useful than any single unidimensional scale. Inclusion of too large a number of variables may obscure discrimination just as easily.

Considering the recent evidence by Wakefield et al. (1974) that the primary MMPI subscales may be fully accounted for by Eysenck's dimensional personality model, it

Table 3
Correlations of the MMPI-Derived TSC Scales With Two Discriminant Functions and Tests of Significance for Three Subgroups of Day-Care Patients

Scale	Discriminant function		Univariate <i>F</i>	<i>p</i>
	1 ^a	2 ^b

* $p < .05$ (two-tailed).

** $p < .01$ (two-tailed).

is of interest to note the intercorrelations shown in Table 4. Evidently, the second-order Neuroticism factor is strongly correlated with the factorially pure MMPI validity scales. Had these been corrected for attenuation, the multiple correlation values would have been substantially higher. This moderately high relationship, in terms of shared variance, between the two inventories partially explains why the comparatively short EPI suffers little or no loss in overall predictive power (68.15% vs. 66.24%). The results reaffirm that a good deal of "collinearity" exists between Eysenck's personality traits and psychiatric disorders, as measured by symptom-sign questionnaires such as the MMPI—sufficiently so, it would appear, to suggest that the emphasis on dimensional over categorical criteria is not misplaced.

Analysis 2: Continuum of Severity

Twenty-five variables. The measure of intergroup dispersion, Wilk's lambda, as shown in Table 1, was significant ($p < .001$). Two roots emerged to account for 75.5% and 24.5% of the between-group variance, respectively. The first function had moderately high weightings on Moral Self; Self-Criticism; Social Introversion; Depression; Tension, Worry, and Fears; and the MMPI Lie scale.

Figure 2. Dimensional profile of 28 low, 46 median, and 83 high-level Neuroticism (N) patients based on 25 predictor variables. (Latent roots: $\lambda_1 = .448$ (75.5%), $p < .001$; $\lambda_2 = .764$ (24.5%), $p < .016$.)

This combination is somewhat suggestive of the intermediate forms of behavioral disturbance usually attributed to the dysthymic personality (i.e., those patients whose problems focus on phobic, anxious, depressive, or obsessive concerns).

The second function was positively loaded by Suspicion-Mistrust, Autistic Thinking, Resentment-Aggression, the MMPI Lie scale, and Extraversion, and negatively by Social Interest. This configuration seems to allude to the distorted reality contact, social deviance, and depersonalization commonly found at the higher endpoint of the normality-psychoticism spectrum. Such vectors may well signal the diffuse, yet quantitative, level at which extreme forms of normal thinking and feeling processes fade into gross psychologic abnormality. If this is indeed the case, it is expected that the more highly disturbed patients would occupy this region of the severity continuum. On any such continuum would lie

the commonly referred to, though vague multiple diagnostic types like pseudoneurotic schizophrenia, schizophreniform personality, chronic anxiety depression, or alcoholic psychosis-paranoid type. These could well be dropped as they simply add to the internal contradictions of categorical psychiatry.

An inspection of Table 5 indicates that for the diagnostic model, only 12 of 26 clinical predictor scales significantly distinguished between the three conceptual typologies. However, for the "degree" of severity continuum, 18 of 25 (excluding Neuroticism itself) predictor variables register a significant level of discriminant validity. Two TSC scales (Tension, Worry, Fears and Resentment-Aggression) were the most powerful predictors for the dimensional analysis. The dimensional approach, even in the present limited context, yields more encouraging results, suggesting that patients can more easily be aligned on a continuous maladjustment axis. Conversely, the search for "pure" or sharply demarcated subtypes not only leads to the misapplication of a science but encourages widespread criticism.

Of considerable interest are the individual points in multiperson space seen in Figure 2. Of the three ellipsoids, one contains all but 3 low Neuroticism cases. The second region contains, with 4 exceptions, the 46 patients divided at their median Neuroticism levels. The third zone is occupied by, with the exception of 7 moderately disturbed patients positioned in the second region and 1 stray subject assigned to the lower end of the continuum, all of the most debilitated patients with highly elevated Neuroticism profiles. There is an impressive degree of separation along the unbounded severity continuum ($p < .001$ by Fisher's exact test) for all three levels of general maladjustment.

In terms of classification efficacy, Table 6 shows that the dimensional model is able to portray the patients' loci in n -dimensional space with 90.44% accuracy taking, as a putative index, each subject's level of Neuroticism. Dimensional analysis, it seems, brings out the "real" covariations with sharper clarity. Naturally, this illustrative procedure remains to be carried out with other carefully

*** $p < .001$.

chosen factors for even broader discriminability. If actually more realistic, the dimensional view of personality would, obviously, have to be augmented by sensitive tests of physiological, biochemical, and cognitive functioning.

MMPI scales. The seven TSC scales were combined into a prediction formula that produced two canonical variates; both latent roots were highly significant. Dimension 1 accounted for 64.3% of the variable ($\lambda = .666$), $\chi^2(14) = 50.76$, $p < .001$; whereas the second function accounted for the residual

35.7% of trace ($\lambda = .793$), $\chi^2(6) = 25.42$, $p < .001$. The group centroids (or mean discriminant scores) are illustrated in Figure 3. As previously shown, taking each patient's degree of neurotic variability results in an optimal *interdimensional* (as opposed to *intergroup*) dispersion to pinpoint the locus of 85.35% of all psychiatric patients compared to the 68.15% correct consensus achieved for the diagnostic criterion. Were it not for the relatively high proportion of dysthymic neurotics positively identified, the percentage range would surely have fallen into the mid-

Table 6
Dimensional Dispersion of Patients on a Neuroticism Severity Continuum for Global Versus Tryon-Stein-Chu Diagnostic Scales

Measure	Actual Neuroticism group	Predicted group membership		
		1	2	3
26 variates ^a	Low	25 (89.3)	3 (10.7)	0 (0.0)
	Moderate	1 (2.2)	42 (91.3)	3 (6.5)
	High	1 (1.2)	7 (8.4)	75 (90.4)
7 MMPI scales ^b	Low	24 (85.7)	3 (10.7)	1 (3.6)
	Moderate	3 (6.5)	37 (80.4)	6 (13.0)
	High	2 (2.4)	8 (9.6)	73 (88.0)

Note. Numbers in parentheses are percentages. For Low Neuroticism, $n = 28$; for moderate Neuroticism, $n = 46$, for high Neuroticism, $n = 83$. MMPI = Minnesota Multiphasic Personality Inventory.
^a $\chi^2(4) = 182.79, p < .001$; 90.44% of cases were correctly identified.
^b $\chi^2(4) = 119.13, p < .001$; 85.35% of cases were correctly identified.

dle 50s or 60s in line with those shown for the alcoholic and schizophrenic groups.
Across diagnoses, then, the number of cor-

Figure 3. Dimensional position of 157 psychiatric patients on a Neuroticism (N) severity continuum predicted from seven Tryon-Stein-Chu scales. (Latent roots: $\lambda_1 = .666$ (64.3%), $p < .001$; $\lambda_2 = .793$ (35.7%), $p < .001$.)

rectly identified cases for the global dimensional analysis, and seven-variable TSC battery, is clinically superior to that of psychiatric discriminability. Noticeably, the less impressive evidence for the reliability of the diagnostic concepts, as compared with objective laboratory tests, is based on only a conservative number of hospital patients and, as such, needs to be replicated on larger sample sizes, related indices of psychopathology, and alternate experimental designs.
A measure of the observed relations between the assigned psychiatric diagnoses and computer classification matrix was also determined (see Table 7). The Kappa coefficient can be described as an interclass correlation that gives the proportion of diagnostic agreement corrected for chance (Fleiss & Cohen, 1973). For the 26-variable analysis, weighted $K = .500$, rising to .843 for the dimensional approach. Clearly, Kappa for the dimensional analysis is significantly larger ($p < .01$) than Kappa for the diagnostic classification matrices. Notably the weighted Kappa values for the DSM-II diagnostic codes are only slightly higher than those reported by Fleiss, Spitzer, Cohen, and Endicott (1972) for similar psychiatric categories. The magnitude of these values is generally in the lower range expected for well-trained psychiatric personnel. The implication for the clinician is that it may be easier to depict patients in terms of their degree of psychopathology along a num-

ber of continuously variable dimensions than to fit patients into predetermined classes.

Discussion

Unlike studies that have sought to affirm that clinical diagnostic profiles are etiologically distinct, the present study offers some provisional evidence that aligning psychiatric patients along a severity continuum, namely, "degree" of Neuroticism is somewhat superior to allocating them into diagnostic categories. This may possibly apply to Eysenck's Psychoticism factor as well. Such a distinction, doubtless, rests on the extent to which conceptually derived stereotypes coincide with the clinician's experience of the observed characteristics of actual patients. In many instances, T data (objective tests) and L data (life behavior, rated) are used to verify the diagnostic nomenclature, yet they report only nominal agreement. Considering the minor tolerances of empirical methods due to peculiarities of observation, methods of data analysis, and varying sample characteristics, there seems a limit to what even a perfect diagnostic test could do when compared against the psychiatric criterion used. The fairly poor agreement, as reflected in the weighted Kappa values shown in Table 7, raises the issue of whether the broad typologies have any clinical utility beyond that evident for a dimensional model of personality functioning.

In terms of clinical utility, the general equivalence of the EPI to a factorially pure MMPI is rather encouraging, even though the former was not constructed specifically with a view to replicating psychiatric diagnoses. This congruence is reassuring, since both instruments denote separate approaches to personality assessment that converge at the multivariate level. Owing to the larger number of critical distinctions shown in Table 5, it appears that the decision rule to use a patient's degree of emotional instability on a continuum of regression from normality "teases" out some of the real differences much more sharply, and with less obscurity, than a categorical reference system. The two discriminant functions, in com-

Table 7

Overall Agreement (Mean Weighted Kappa) Between Diagnostic Versus Dimensional Profiles Generated by Discriminant Function Analysis for Three Psychiatric Subgroups

Scalar combination	% correctly assigned	M reliability (weighted Kappa)
Diagnostic profile		
26 variates	70.70	.500
7 MMPI scales	68.15	.455
2 EPI scales	66.24	.426
Severity continuum		
25 variates	90.44	.843
7 MMPI scales	85.35	.759

Note. The Neuroticism factor itself served as the putative criterion, leaving only 25 predictors for the global dimensional analysis. MMPI = Minnesota Multiphasic Personality Inventory.

bined form, capture 90.44% of the interdimensional continuity of this major personality factor.

Abolition of diagnostic categories, it is often argued, involves loss of clinical-descriptive, social, and etiological data, including the predictions about outcome and treatment response implied by the original diagnosis. Yet, critics of the dimensional model ignore the fact that *modal profiles* explain lawful covariations between normal and psychologically ill persons in a more meaningful way. All psychiatric diagnoses have their own "degree of certainty," which varies according to whether the etiology is fragmentary or well defined. As few psychiatric phenotypes are immutable, mutually exclusive, or nonreflexive, the art of diagnosis remains a fallible decision process founded on the assumption of *homogeneity* of psychiatric disease types—a still largely unproven axiom. Evidence now emerging from the "spectral analyses" of alcoholic, depressive, and antisocial patient groups strongly suggests, in many cases, that such phenotypes are plainly *heterogenous*, with fairly unknown etiology and neurophysiologic basis.

Notably, assigning any person into a predetermined class, apart from the harmful

effect of an erroneous diagnosis (Morrison & Flanagan, 1978), presupposes much loss of idiographic data, for few labels reflect all the content. Whatever dimensional model is eventually chosen would need to compensate for this loss by providing specific details on the interdimensional axes relevant to the patient's varied symptomology. The patient's prodromal signs would serve to guide clinicians in their choice of the "number of continua needed" problem.

Some recent research has already focused on the extent to which variable hierarchies of personal illness do exist (Foulds & Bedford, 1975) and the degree to which symptom patterns can be fitted within a broader dimensional personality system (Eysenck & Eysenck, 1976). Further study of personality functioning within a combined *hierarchical-dimensional* context may well take us on the path to a scientific realism. This, perhaps, is one of the foremost tasks awaiting present-day behavioral scientists. Paradoxically, early psychiatric theory, has had to undergo a good deal of revisional thinking, as it found itself faced with a large number of overlapping intermediate conditions that did not fit the classical concept, particularly the syndromes. In their everyday experience, clinicians hear far too rich and varied material to fit into discrete or bipolar categories. The lack of strict diagnostic criteria by which to codify the abnormal aspects of human behavior suggests that the pretension to a scientific psychiatry is weakly defensible. Under more careful scrutiny, it is usually only the pure cases—like the Cotard or Capgras syndromes—to which the patient has been assigned, Procrusteslike, that are uniquely categorical. And any such unicorns are rare indeed!

In the personality domain, certain higher order factors such as Neuroticism (otherwise known as anxiety or general emotionality as some prefer) occur in the general population continuum with predictable frequency. The predisposition of being affected will vary according to the degree of stress that each individual can tolerate. A. E. Maxwell (1971) showed that neurotics, affective psychotics, and schizophrenics all exhibited a basic core of symptoms of the type generally

referred to as neurotic. Likewise, Vaz Serra and Pollitt (1975) found that the level of Neuroticism for 100 depressives increased proportionately with their level of depression (as measured by the Beck Depression Inventory), whereas the reverse was true for Extraversion. This is in perfect accord with the present findings.

More likely than not, the plotting of *dimensional profiles* can be effectively applied to the treatment process by providing clinical data on symptom elevation, so as to schedule patients into optimal treatment regimes. Patients could simply be referred to a specific treatment modality depending on the relative position that they inhabited within a multidimensional grid. Apart from simply projecting a subject's scores on personality traits alone into a hypergeometrical space, more precise biological variables such as level of sedation threshold, blood gases, skin conductance, electroencephalogram and electrocardiogram anomalies, blood pressure, or extrapyramidal arousal could be included to pinpoint a person's unique dimensional profile. In this way, the less debilitated person would readily be distinguished from the more severely disturbed person. A person's dimensional position, in the hyperspace defined by the major coordinates selected, would thus govern critical treatment decisions about drug dosage levels, degree of psychopathology, nature of neurological impairment, or ability to benefit from the various forms of therapy. The patient's degree of reality contact, self-assertion, or capacity for love, as assessed by objective laboratory tests and systematic observation techniques, would help determine the client's response to treatment. As this growing body of knowledge evolves from hypothesis to theory to empiricism to culminate as scientific law, the advantages of an applied dimensional approach can be more formally addressed.

Extending the argument, it has been shown that schizophrenics with high levels of autonomic arousal (high sedation threshold) exhibit more paranoid features, whereas those with low levels (low sedation threshold) tend to be retarded, affectively flattened, and socially withdrawn (Claridge, 1972). More

importantly, Claridge emphasized evidence which suggests that certain central nervous system parameters in those predisposed to schizophrenia not only covary together differently in their organizational structure, rather than deviations, but show continuity between normal and pathological thinking. This also applies to normal, neurotic, and psychotic patients as well. Much like personality traits, "many biological phenomena are continuous variables" (Lader, 1975, p. 75). Others, such as Weckowicz, Yonge, Cropley, and Muir (1971), have demonstrated the importance of *level* of arousal and symptom *severity* for choice of treatment, whereas level of neuroticism or psychoticism is a more valid predictor of treatment and outcome of depressive illness than is diagnosis (Kendall, 1969).

Patients who exhibit irrational mental processes or cyclic mood fluctuations (e.g., elation-depression) could readily be delineated on a sympathetic arousal continuum, together with any other relevant features, to distinguish both hypomanic and dysphoric states from normal excitatory states. Aside from simple linear deviation along an "arousal continuum," the *hierarchical organization* of central nervous system processes, as a causal determinant of the atypical personality, can be studied within the context of a dimensional framework. Psychiatric abnormalities can be arranged in a hierarchy (like a Thurstonian taxonomy) to enable a more detailed study of how changes in clinical symptomology *covary* with higher order personality traits. For the most part, many forms of bizarre behavior and psychotic thinking processes appear to exist as continuities of regression from normality, not discontinuities. As such, the deviation from normality is quantifiable, rather than being defined by qualitative change points. Moreover, the dysfunctional personality features can be dimensionally rather than categorically defined, with no loss of vital clinical details. If indeed more realistic, one may wonder why the dimensional view of abnormal personality functioning is not more widely adopted as a suitable replacement for the psychiatric reference system.

As modal profiles, based on dimensional

analysis of normal and psychiatrically ill populations are standardized, with wide generalizability, the clinician will be able to speedily calculate the probability associated with each level (or stage) of symptom severity, either by means of an accessible computer terminal or a handy desk calculator. As data are accumulated for the underlying continuum of clinical pathology, dominant symptoms, mood elevation or depression, and fluctuating delusional states would, of necessity, each have their own set(s) of frequency distributions and tests of significance for the critical parameters under study.

Above all, a purely disease-entity model does not reflect the "best fit" of the conceptual nosology to the *actual* empirical features of the general population continuum. Instead, in its place, a dimensional system of personality functioning, sufficiently modernized, would permit the helping professional to portray psychiatric abnormality in a scientific context, and thereby facilitate evaluation and treatment. To this end, daily clinical judgments that affect treatment strategies and therapeutic outcome would thus be made with an impressive degree of certainty. Given a broader scope, the development of applied dimensional models of behavior and personality remains an intriguing research topic.

Cued Recall and Discrimination of Memory Deficit

P. Rawling

St. Vincent's Hospital, Sydney, Australia

J. G. Lyle

University of Sydney, Australia

Some ambiguities in the scoring procedure for the Logical Memory subtest of the Wechsler Memory Scale were eliminated by adopting a cued recall technique for eliciting responses. A cued recall technique discriminated significantly better than the Logical Memory subtest between memory-impaired and control groups. This appears to have been due to the fact that on Logical Memory, controls showed worse performance on the final sections of the memory passages, whereas this did not occur in cued recall.

The Wechsler Memory Scale (WMS) has an important place in clinical assessment, since despite the restricted size of the normative population and the small variances on some of the subtests, it is one of the few memory tests that is generally available. One of the more important of the WMS subtests is Logical Memory. A number of factor analytic studies have shown that this subtest, together with Associate Learning and Visual Reproduction, load on a factor involving the acquisition and immediate recall of complex stimuli, and that of the seven WMS subtests, these three subtests appear to be the most useful in the detection of cerebral dysfunction (Bachrach & Mintz, 1974; Kear-Colwell, 1973).

In the case of the Logical Memory subtest, however, there are several weaknesses and ambiguities in the administrative and scoring procedures that affect its reliability, validity, and hence its clinical utility. (a) The division of the story into memory units is essentially an arbitrary procedure. (b) The scoring criterion is poorly defined; it is left to the clinician to decide whether synonyms, paraphrasing statements, or approximations should be credited. (c) Many studies sug-

gest that in recalling meaningful prose, subjects will reconstruct a story so as to keep the general theme intact rather than attempt to reproduce it verbatim. Summing the number of words or memory units reproduced verbatim from the original passage may not appropriately assess this style of recall.

This study began as a practical attempt to devise and test a modified version of the Logical Memory subtest that would avoid some of the shortcomings outlined above. A cued recall procedure was devised whereby the subject would be presented orally with a standard list of questions after the reading of each passage. Subjects no longer needed to be uncertain whether they were meant to recall the gist of the passage or attempt to recall it verbatim. In addition, by providing a detailed statement of the scoring criteria for each of the standard questions, the objectivity of scoring such a test should be greatly enhanced.

Subjects (all males) were selected from a local Veterans hospital. Excluded from the study were those who were disorientated or who suffered any motor, linguistic, or psychiatric symptoms likely to interfere with performance on the test battery. Subjects were allocated to the memory deficit and control groups on the basis of their performance on two standardized memory tests, one involving recall of a number of pictures (Simpson Memory Pictures) and the other involving recall of a sequence of meaningless shapes (Simpson Shapes Test). This em-

The authors would like to thank F. N. Simpson, Senior Psychologist, Department of Veterans Affairs (Sydney) for permission to use tests and normative data prior to publication.

Requests for reprints should be sent to Peter Rawling, c/o Caritas Centre, St. Vincent's Hospital, New South Wales 2010, Australia.

pirical method of subject allocation was adopted in recognition of the fact that documented evidence of a cerebral lesion is, of itself, no guarantee of memory loss. All subjects were also administered the Simpson Adult Vocabulary Scale as a control measure of intelligence, since it is known that vocabulary tests are relatively resistant to aging and dementia.

Finally, two groups of subjects were selected. The age range of the subjects was 50–64 years; mean age of the deficit group was 56.73 years ($SD = 3.84$) and 57.40 years for the control group ($SD = 4.03$). The mean IQ of the deficit group was 97.67 ($SD = 11.12$), and for the control group it was 99.37 ($SD = 10.75$).

Both passages of the Logical Memory subtest of the WMS and a modified version of this test involving cued recall by means of standard questions were administered. Two prose passages that comprised cued recall differed in content from those of Logical Memory so that there would be minimal transfer of learning from one to the other. All five tests were administered in a counter-balanced order to avoid order effects; cued recall and Logical Memory were never administered consecutively. Raw scores of Logical Memory and cued recall were converted to *T* scores for direct comparison of means and standard deviations. These scores were subjected to analysis of variance.

Mean scores for Logical Memory were 45.24 for the deficit group ($SD = 8.05$) and 55.15 for the controls ($SD = 8.71$). Mean scores for cued recall were 42.42 for the deficit group ($SD = 6.10$) and 57.61 for the controls ($SD = 6.22$). A split-plot analysis of variance, in which the main effects were groups and tests, was carried out on the standardized scores. The focus of interest in this analysis was the Groups \times Tests interaction, which was significant, $F(1, 58) = 5.48$, $p < .05$. This indicates that cued recall differentiated between the groups significantly better than did Logical Memory.

Further examination of the discriminating value of Logical Memory and cued recall was carried out by comparing group recall scores for the initial, middle, and final thirds of each separately. For Logical Memory, the

two passages were each divided into thirds according to the total number of memory units, and the number of units recalled from each third were then summed across both passages. For cued recall, three questions related to the content of each third of each passage; part scores were the sum of questions correctly answered from each third of both passages.

Split-plot analyses of variance, in which the main effects were groups and parts, were carried out on Logical Memory and cued recall separately. Logical Memory significantly discriminated between the groups, $F(1, 58) = 18.46$, $p < .001$; the parts of the test differed significantly, $F(2, 116) = 13.47$, $p < .001$; and there was a significant Groups \times Parts interaction, $F(2, 116) = 6.08$, $p < .01$. The two groups were discriminated by Logical Memory significantly better in the first and middle thirds of the passages than they were in the final third. Cued recall discriminated between the groups highly significantly, $F(1, 58) = 132.00$, $p < .001$; there was a significant difference between parts of the test, $F(2, 116) = 18.91$, $p < .001$ (with the first third being better recalled than the final third); but the Groups \times Parts interaction was nonsignificant. It was apparent from the analysis that the superior discrimination of cued recall relative to Logical Memory was due to the fact that recall of the controls reduced sharply in the final third of Logical Memory, whereas in cued recall the separation of the groups was maintained throughout the test.

In summary, it was found that a modified version of the Logical Memory subtest of the WMS, in which a cued recall technique was used, discriminated between a memory-impaired group and a control group significantly better than did the standard Logical Memory subtest. This was due to the reduced performance of the controls on the final third of the prose passages of Logical Memory, which may have been the result of proactive inhibition, whereby the recalling of the earlier sections interfered with recall of the final sections.

It was noted qualitatively that three types of errors seemed to characterize the memory-impaired group. (a) *Generalization*: This oc-

occurred when patients responded in the right category but were inaccurate; for example, Smith in lieu of Jackson; 10 o'clock in lieu of 2:30. The controls made 12 such errors, whereas the deficit group made 40 such errors. This finding is contrary to that of Talland (1965), who found that this type of error did not discriminate between impaired and normal groups. (b) *Fabrication*: This occurred when patients introduced material that was not in the original passage. This type of response occurred 8 times in the deficit group and once in the control group. (c) *Contamination*: Here, material from Passage A was given in response to questions pertaining to Passage B. Patients from the

deficit group made 3 such errors, control group patients made no such errors.

Effects of Differences in Suggestibility Within Self- and External-Control Conditions

Gary T. Souheaver and W. John Schuldt
University of Arkansas

This research was designed to study possible effects of differences in waking suggestibility on performance within self- and external-control conditions. Ten high-suggestible subjects and 10 low-suggestible subjects, as measured by body sway, were assigned to each of three experimental conditions—self-control, external-control, and no reward. Response rates of self and external groups were higher than the no-reward group. However, response rates of high-suggestible subjects in the self-control condition were not significantly different than similar subjects in the no-reward group. Moreover, performance of high- and low-suggestible subjects was not significantly different in the external-control condition. *Keywords:* suggestibility, self-control, external-control. High-suggestible subjects in the self-control condition.

Suggestibility, in a hypnotic state and in a normal waking state has long been of clinical interest. Moreover suggestibility has been investigated within a wide range of experimental conditions and populations (e.g., Barber, 1963; Dargatzis & Nassis, 1973; Eysenck, 1967; Jones & Hagen, 1971; Morgan & Hirsch, 1971; Veltman, 1974; Webb, 1975; Weissman, 1973). However, in a review of suggestibility Evans (1967) indicated that the literature on the relationship between suggestibility and conditioning was desultory.

One study that the existence of a relationship between waking suggestibility and response rates in external conditioning is reported by Rasmussen & Hill (1961). They found that high-suggestible subjects, as measured by body sway, responded more frequently to a tone than low-suggestible subjects. This relationship was not observed in a study by Webb (1975).

This study is based on a design suggested by the first author in the first section of the second section of the manuscript. It is a study of the relationship of waking suggestibility and response rates.

Keywords: suggestibility, self-control, external-control, body sway, response rates, waking suggestibility, conditioning.

Weiss, Ullman, & Krasner, 1960). Thus, waking suggestibility may not be related to acquisition of responses, but it may serve as a moderator variable for modification and/or maintenance of existing behavioral patterns.

This view seems congruent with Thoresen and Mahoney's (1974) view that suggestibility may influence self-regulatory strategies. Moreover, it seems consistent with Tolor's (1971) evidence that high-suggestible subjects are externally oriented.

Even though there is evidence that self-reward versus external reward occurring within operant conditioning procedures has little differential effects on performance (Bandura & Perloff, 1967; Liebert, Speigler, & Hall, 1970), there have been no systematic attempts to examine possible effects of differences in waking suggestibility on performance within self- and external-control conditions. Thus, this research was designed to assess the effects of self-control and external control of rewards within groups of subjects who differ in levels of waking suggestibility. Specifically, the following hypotheses were tested: (a) There will be more responding in self- and external-control conditions than in no-reward conditions, (b) high-suggestible subjects will respond more to external control conditions than will low-

suggestible subjects, and (c) low-suggestible subjects will respond more to self-control conditions than will high-suggestible subjects.

Method

Subjects

Sixty volunteer undergraduate students, single and between the ages of 18 and 25, participated as subjects. Restrictions on age and marital status were imposed, since suggestibility has been found to vary as a function of these variables (Morgan & Hilgard, 1973).

Apparatus

The index of suggestibility was postural body sway. An apparatus, similar to that described by Webb (1962a), was designed to convert horizontal body movement into movements of a marker along a vertical scale; that is, a nylon string attached to the subject's collar activated an ink marker positioned behind the subject.

Apparatus for the self-reward, external-reward, and no-reward conditions was similar to that described by Liebert et al. (1970). The subject was seated in front of a panel that contained two parallel columns of lights—20 red lights on the left and 20 green lights on the right. Adjacent to each fifth pair of lights, the numbers 5, 10, 15, and 20 were printed in ascending order. The subject activated the red lights (which served to indicate the criterion for delivery of reward) by turning a criterion selector knob at the center of the panel to one of four positions corresponding to the selected criterion. The green lights were successively lit by turning a hand crank positioned in front of the subject. Two complete clockwise turns activated one green light. When the subject turned the crank enough times to reach the preset criterion, lights on both columns extinguished to signify the end of a trial. A storage container for rewards (tokens) was placed adjacent to the nondominant hand of the subject.

Procedure

Each subject was initially requested to stand, facing a blank wall, on a floor marker 4 feet (1.2 m) from the suggestibility apparatus. After the body sway string was attached to the subject's clothing, he/she was told to close the eyes, relax, and allow both hands to hang loosely at the side with both feet together. The subject was told that he/she would not be shocked, injured, or embarrassed in any manner. The following instructions were presented for 2.5 minutes on a tape recording

played on a standard cassette player:

I want you to listen carefully to what this tape says while you go on just standing there, quite still and relaxed, with your eyes closed. Now, just keep standing there please, quite still and relaxed with your eyes closed, and think of nothing in particular. Just keep standing there quite still and relaxed, and listen to me. Now I want you to imagine that you are falling forward, you are falling, falling forward, falling forward all the time. . . . (adapted from Eysenck, 1947)

Subjects whose body sway exceeded 2 inches (5.1 cm) were considered high suggestible; those who swayed less than 2 inches were considered low suggestible. These operational definitions of suggestibility are consistent with those of Eysenck (1947). Ten high-suggestible subjects and 10 low-suggestible subjects were assigned to each of the three experimental conditions—self-control, external control, and no reward.

Procedures for the self-control and external-control conditions were similar to those of Bandura and Perloff (1967). Subjects in the self-control condition were allowed to select their own reward criterion and to self-administer tokens. These subjects were instructed to choose their performance criterion on the reward apparatus, and whenever the criterion was attained by turning the crank, they were to give themselves a token with the nondominant hand by placing it in the token container. They were also told that these tokens could be exchanged for money, at the rate of one penny per token, at the end of the experiment. Subjects in the self-control condition were told that they could change the performance criterion only once, either higher or lower.

Subjects in the external-control condition did not select a reward criterion. Rather, their criterion was individually yoked with self-control subjects. This allowed for a control of possible reinforcement scheduling effects. External-control subjects were told that they would receive tokens, exchangeable for pennies, each time they turned the crank a sufficient number of times to turn off the red light. Each time the criterion was reached, the experimenter placed a token in the storage container.

Subjects in the no-reward condition were also individually yoked to subjects in the self-control condition. They were told to turn the crank with the dominant hand. Performance was not rewarded with tokens.

Results

Body sway means for high-suggestible subjects [3.58 inches (8.9 cm)] and low-suggestible subjects [1.01 inches (2.5 cm)] were significantly different, $t(58) = 11.74$, $p < .001$. Mean ages of the groups (high

suggestible = 19.10; low suggestible = 19.70) did not differ significantly ($t < 1$). Moreover, mean grade point average of 2.84 and 2.82 for high- and low-suggestible subjects, respectively, did not differ significantly ($t < 1$).

The dependent measure for the three experimental conditions was number of crank turns performed by each subject within 4 minutes (Liebert et al., 1970). Means for each treatment, at both levels of suggestibility, are presented in Table 1.

Since it was predicted that self-control and external-control subjects would respond more than no-reward subjects, regardless of levels of suggestibility, an analysis of variance, collapsing across levels of suggestibility, was conducted. Self-control and external-control subjects manifested significantly greater performance than did no-reward subjects, $F(1, 54) = 14.27, p < .001$.

Dunnett critical differences tests (Keppel, 1973) were used to compare responses of no-reward subjects to subjects within each reward condition at each level of suggestibility. Mean performance of low-suggestible subjects in both the external-control self-control conditions was significantly greater ($p < .05$) than low-suggestible subjects in the no-reward condition. High-suggestible subjects in the external-control condition responded significantly more than did high-suggestible subjects in the no-reward condition ($p < .05$). However, high-suggestible subjects in the self-control condition did not perform significantly more than did high-suggestible subjects receiving no-reward ($p > .05$). Thus, conditioning was not evident for high-suggestible subjects in the self-control condition. It was also predicted that high-suggestible subjects would respond more than low-suggestible subjects in the external-control condition and, conversely, that low-suggestible subjects would respond more than high-suggestible subjects in the self-control condition. High-suggestible subjects did not respond significantly more than low-suggestible subjects in the external-control condition ($t < 1$). However, low-suggestible subjects did respond significantly more than high-suggestible subjects in the self-control

Table 1
Mean Number of Turns

Suggestibility level	Treatment group		
	Self	External	No reward
High	218.20	250.70	172.00
Low	276.40	268.40	126.00

treatment, $t(18) = 2.11, p < .05$. No significant difference was noted between high- and low-suggestible subjects within the no-reward treatment, $t(18) = 1.42, p > .05$.

Discussion

This study demonstrated that increased responsivity resulted with either self-control or external-control procedures when levels of suggestibility were disregarded. However, there was no evidence of conditioning for the high-suggestible subjects in the self-control condition. Thus, self-control procedures may not be equally as effective as external-control procedures when "personality" variables are considered.

It was hypothesized that high-suggestible subjects would respond more to external control than would low-suggestible subjects. This prediction was based on the conceptualization that high-suggestible persons are more susceptible to influence from others and, therefore, are more amenable to external imposition of standards and rewards to increase performance levels. However, the results of this study do not support this prediction; that is, the high- and low-suggestible subjects responded at essentially the same rate in the external-control condition. This finding is not congruent with the findings of Webb (1962b) and Weiss et al. (1960), who reported that high-suggestible subjects did respond more than low-suggestible subjects under response-contingent external reward conditions. These studies, however, used verbal praise as rewards in verbal conditioning procedures. The present study, in contrast, used tokens as rewards in an effortful motor task. Thus, differences in procedure may account for the apparently discrepant results.

Another hypothesis was that low-suggestible subjects would respond more to self-control than would high-suggestible subjects. This prediction was based on the conceptualization that low-suggestible persons are less susceptible to influence from others and are, therefore, less likely to require external imposition of standards and rewards to increase performance rates. The results were consistent with this prediction.

Based on the results of this research, one can speculate that low-suggestible persons respond equally well to either self- or external demands and rewards, whereas high-suggestible persons are so dependent on external factors that their performance is minimal when self-determination of reward contingencies is required. Moreover, self-delivered rewards may not have reinforcement value for high-suggestible persons when they are allowed to determine their own standards.

Our findings, if supported by future research, would seem to have clinical significance. For example, it appears that either external-control or self-control techniques would be effective with low-suggestible clients. Additionally, it would seem that high-suggestible clients would not initially benefit from psychotherapy procedures in which self-control is advocated or imposed. However, caution is urged in applying these preliminary findings to clinical practice, since there is a lack of research relating suggestibility to self-control and because this study may have considerable analogue error.

Self-Directed Treatment for Premature Ejaculation

Robert A. Zeiss
University of Oregon

One promising variation of the now standard Masters and Johnson approach to treating premature ejaculation lies in the use of self-administered treatment manuals. In a test of one such manual, couples with premature ejaculation problems were assigned randomly to (a) totally self-administered treatment; (b) self-administered treatment in conjunction with minimal therapist (telephone) contact; or (c) standard therapist-administered treatment. Couples were successfully treated by therapists or by themselves when they maintained minimal contact with a therapist. Couples working on their own, with no therapist contact, failed to complete treatment successfully. Follow-up data indicated that although there was deterioration in therapeutic gain following the termination of treatment, improvement over pretreatment responses was maintained on all relevant measures. An analysis of posttreatment data indicated that greatest improvement in ejaculatory control occurred when couples continued to use the squeeze or pause to delay ejaculation, but significant improvement in latency to ejaculation also occurred when couples used neither technique to lengthen intercourse.

During the past few decades, a number of approaches to the treatment of premature ejaculation have appeared. These have included strategies relying on pharmacologic intervention (e.g., Aycock, 1949; Bennett, 1961; Boneff, 1971; Mellgren, 1967), as well as strategies relying on psychotherapy (e.g., Cooper, 1969) or combining chemotherapy with psychotherapy (e.g., Friedman, 1968; Schapiro, 1943). In the 1950s, Semans (1956) and Wolpe (1954, 1958) introduced learning-oriented approaches to the problem; these approaches were largely ignored until the work of Masters and Johnson (1970) refined the approaches and revived

interest in the behavioral treatment of premature ejaculation.

Since the Masters and Johnson publication, most research in this area has focused on increasing the efficiency of their highly effective approach (e.g., Clarke & Parry, 1973; Kaplan, 1974; Kaplan, Kohl, Pomeroy, Offit, & Hogan, 1974; Zeiss, Christensen, & Levine, 1978; Zilbergeld, 1975). However, few of these studies have presented any data to support contentions of therapeutic effectiveness and efficiency.

Self-Directed Treatments

A recent and promising direction in the treatment of sexual dysfunction has been the development of behavioral self-help programs written to allow couples to treat sexual problems on their own, without the extensive intervention of a professional therapist. These have included programs for the treatment of general sexual dysfunction (e.g., Kass & Strauss, 1975) and female orgasmic dysfunction (e.g., Barbach, 1975; Heiman, LoPiccolo, & LoPiccolo, 1976; Kline-Graber & Graber, 1975), as well as specifically for

This report is based on a doctoral dissertation submitted to the University of Oregon.

The author gratefully acknowledges the assistance of Debra Jackson-Spangler, Robert Kurlychek, Dennis McClure, Terry S. Trepper, and Katie Whalen, all of whom served as therapists in this study. The encouragement and contributions of Antonette Zeiss were invaluable in all stages of the project.

Requests for reprints should be sent to Robert A. Zeiss, who is now at Valle Del Sol, 1209 South First Avenue, Phoenix, Arizona 85003.

premature ejaculation (Lowe & Mikulas, 1975; Vandervoort & McIlvenna, 1972; Zeiss & Zeiss, 1978). The treatment for premature ejaculation seems particularly amenable to a self-directed format, since it enjoys a high probability of success, is straightforward, and can be easily standardized.

If empirically validated, this type of program has the potential to make effective, yet inexpensive, treatment available to the general public. Unfortunately, data have been reported for only two of the sexual self-help programs (Kass & Strauss, 1975; Lowe & Mikulas, 1975), and only one has been submitted to any controlled evaluation. Lowe and Mikulas (1975) found that couples using a written program in conjunction with telephone contact (of unspecified length) with a therapist reported significant improvement in latency to ejaculation, whereas untreated control couples reported no change in latency. Follow-up data were not reported.

Zeiss (1977) reported on two couples who successfully used a second self-directed program (Zeiss & Zeiss, 1978) in conjunction with minimal phone contact with a therapist (less than 1 hour total per couple) to treat premature ejaculation difficulties. An 8-month follow-up revealed that therapeutic gains maintained.

Even though these studies suggest that self-directed treatment for premature ejaculation may be effective, there were sufficient problems with each to preclude firm conclusions. Lowe and Mikulas (1975) relied only on subjective estimates of ejaculatory latency and did not report on the maintenance of treatment gains or on the amount of telephone contact required. Zeiss (1977) included objective indices of ejaculatory latency, provided an 8-month follow-up, and reported the amount of therapist contact involved, but firm conclusions cannot be drawn from uncontrolled case reports.

Finally, it is unclear exactly what successful treatment of premature ejaculation does. Both the Masters and Johnson (1970) intervention and the Semans (1956) intervention involve teaching clients to interrupt the arousal process, either by applying the

squeeze or by ceasing all stimulation of the penis. It is not clear, however, if greater latency to ejaculation results simply from repeated interruption of the arousal process with squeezes or cessation of stimulation or if practice with these exercises enables clients to tolerate greater and lengthier stimulation without the need for interruption of arousal.

To address these issues, three treatment conditions were compared. One group was treated in a "standard" sex therapy format in which both partners of the dysfunctional couple regularly saw a therapist in the clinic. Two treatment conditions used the Zeiss and Zeiss (1978) manual. Treatment was entirely self-administered for one of these groups; the other group had minimal therapist contact (phone) to increase the probability of successful outcome.

Method

Clients

Twenty heterosexual couples with self-defined premature ejaculation difficulties began treatment. These client couples also met the following criteria: (a) mean timed ejaculatory latency was less than 5 minutes, (b) both partners agreed to participate in the treatment program, (c) the female had no severe gynecological problems, and (d) the couple had experienced the problem for at least 6 months. The 20 couples who began treatment were randomly assigned to one of the three treatment conditions.

Of the 20 couples who began treatment, 2 (1 in each self-directed treatment condition) completed treatment and verbally reported success but failed to complete posttreatment assessment. Because there were no posttreatment data for these couples, they were excluded from all data analyses and further consideration. Data are reported on 18 client couples, 6 in each treatment condition. Demographic and descriptive data for the three conditions are presented in Table 1. One-way analyses of variance revealed that couples in the three treatment conditions did not differ significantly on any of these variables before treatment.

Therapists

Therapists included three male graduate students in counseling psychology and two female BA-level paraprofessionals, in addition to the author (a male graduate student in clinical psychology). Only the author had previously treated couples with sexual dysfunction; the other therapists were trained and supervised by him.

Females	110.7	105.3	100.2

^a In years.^b In seconds.

Procedure

During pretreatment assessment, all couples completed the Locke and Wallace (1959) Marital Adjustment Test and a sexual background inventory. After receiving general information about the study and deciding to participate, couples were asked to report the male's latency from intromission to ejaculation, timed by stopwatch, on two separate occasions of self-defined "normal intercourse."

At a second meeting with their therapist, couples paid a \$10 treatment fee and a refundable contingency deposit of \$30. Refund of the deposit was contingent on regular completion of assignments and completion of posttreatment assessment.

At the conclusion of treatment or after 15-20 weeks from the start of treatment (whichever was earlier), couples again completed the Marital Adjustment Test and the sexual background inventory. In addition, couples timed the male's ejaculatory latency (a) twice as they "normally" had intercourse, reporting the number of squeezes or pauses used each time, and (b) twice during intercourse without using either the squeeze or the pause.

Three months after the completion of posttreatment assessment, the Marital Adjustment Test and the sexual background inventory were mailed to the couples, and couples were asked to complete them.

Treatments

Self-administered manual (no contact). Client couples in this condition were given the treatment

manual (Zeiss & Zeiss, 1978)¹ at their second meeting with their therapist. This manual describes a 12-week training program incorporating the Masters and Johnson (1970) squeeze technique and the Semans (1956) pause technique. During each week, about 3 hours of specific sexual and talking activities are assigned. The talking assignments are intended to facilitate a couple's communication about sexuality and to enhance verbal intimacy. Each week's lesson is followed by a trouble-shooting guide that discusses problems commonly encountered during that week's activities. After an introductory discussion of premature ejaculation and the use of the treatment program, the manual instructs couples in the squeeze and the pause procedures, as well as in sensate focus (Masters & Johnson, 1970), or "pleasuring," exercises. Subsequently, the squeeze and pause are incorporated into the pleasuring exercises to delay ejaculation and to prolong sexual activity in a graduated sequence of sexual interactions. The pleasuring exercises and extravaginal stimulation systematically approach "normal" intercourse, with the expectation that a couple will learn to enjoy ejaculatory control during sexual activity of their own choosing before completion of the program.

Couples in the no-contact condition were encour-

¹ This is a revised version of the manual actually used in the study. The version used by clients in the study was a prepublication draft. This preliminary version can be made available, at cost, to those requesting it from the author.

aged to work diligently and regularly at the treatment program and were told to contact the clinic on completion of the program or earlier if they ran into insurmountable problems. (None actually requested help during treatment.) After 15–20 weeks, all couples were asked to complete the posttreatment assessment.

Self-administered manual with minimal therapist contact (phone contact). This condition involved brief weekly phone contact with the therapist at prearranged times. Total phone contact averaged 71.5 minutes per couple, or about 6 minutes each week. Phone contact was supportive in nature and served primarily to check on couples' progress, to congratulate their successes, to provide encouragement when couples felt discouraged, and to help them resolve minor problems when they arose.

Therapist-administered treatment (standard treatment). In this condition, client couples were seen once weekly, at the University Psychology Clinic, by a therapist. The same specific treatment procedures, exercises, and schedules were used as are described in the manual; treatment was limited to 12–20 therapy sessions of no more than 1 hour each for no more than 20 weeks. The manual was not given to these clients.

Results

Posttreatment

The 18 couples who began treatment and provided posttreatment data were classified as successful or unsuccessful in treatment according to the following criteria: (a) Mean timed latency in normal intercourse must be greater than 5 minutes or must have improved by 3 or more minutes from pretest, and (b) both partners must report improvement in satisfaction with ejaculatory latency. By these criteria, 11 of the 18 couples were successful in treatment. All couples in standard treatment and 5 of 6 couples in the minimal phone contact condition successfully overcame their premature ejaculation problems, whereas none of the 6 couples using the manual entirely on their own was successful. Most couples dropped out early in treatment, typically stating that they were too busy with other activities to devote enough time to the treatment and that they would return to it when their busy lives allowed. Couples who dropped out of treatment were offered treatment in one of the successful treatment conditions, but none accepted the offer. Only 1 couple in the no-contact condition completed treatment. This couple was rated as unsuccessful, despite improvement in latency, because the

^b $n = 5$.

female partner did not report improvement in her satisfaction with the male's ejaculatory latency.

Additional analyses compared the effectiveness of standard in-clinic treatment and self-directed treatment with phone contact, using two-factor repeated measures analyses of variance (unweighted-means solution) comparing pretreatment and posttreatment information. The first of these analyses examined mean timed ejaculatory latencies. This analysis showed a strong main effect from pretreatment to posttreatment, $F(1, 9) = 21.24$, $p < .005$ (means appear in Table 2). There were no significant differences between treatments or interaction effects. A similar analysis of variance was computed using couples' estimates of ejaculatory latency (averaged across the two partners). This analysis also indicates a significant main pre-post effect, $F(1, 9) = 66.74$, $p < .001$, and no interaction or differences between treatments. Mean latency estimates are shown in Table 3.

Analyses of variance revealed no significant change on the Marital Adjustment Test (Locke & Wallace, 1959) either for males or for females. The effects of successful treatment for premature ejaculation on the general sexual relationship were assessed through consideration of the sex quality composite scores. This index is composed of questions from the Sexual Background Inventory (pre or post), chosen on an intuitive, *a priori* basis.² Analyses of variance revealed signifi-

² For males, the index consists of items concerning frequency of intercourse, usual length of foreplay, frequency of premature ejaculation, satisfaction with ejaculatory latency, anxiety over ejacu-

cant main pre-post effects on this variable, both for males, $F(1,9) = 91.71$, $p < .001$, and for females, $F(1,9) = 41.59$, $p < .001$. There were no significant differences between treatments or interactions for either sex. Mean scores on this variable are shown in Table 4.

Maintenance

Of the 11 couples who were successfully treated, 8 returned follow-up data at a mean of 4.4 months (range = 3-9 months) after posttreatment assessment. Of the 8 couples who provided follow-up data, 4 were classified as successfully treated at the time of follow-up on the basis of the two criteria described previously. Three of these couples had received standard in-clinic treatment for premature ejaculation, and 1 had self-directed treatment with phone contact. The other 4 couples (2 in each condition) were classed as no longer successful either because estimates of ejaculatory latency (averaged across the two partners) no longer reached criterion and/or because one of the partners reported

no improvement (over pretest) in their satisfaction with ejaculatory latency.

Of all couples completing the follow-up assessment, two couples reported the same latency as at posttreatment, and six couples estimated their latency to be less than at posttreatment. The differences between the two mean estimates (8 min 11 sec at posttreatment and 4 min 31 sec at follow-up) was significant by a t test for paired observations, $t(7) = 3.81$, $p < .005$, indicating that ejaculatory latencies did decrease in the months following treatment. However, despite the decrease in latencies, follow-up estimates of latency remained significantly greater than pretreatment estimates ($M = 1$ min 43 sec at pretreatment), $t(7) = 3.47$, $p < .01$. A correlation between the two measures (.58) indicated that posttreatment latencies were largely predictive of follow-up latencies.

The sex quality composite scores for these

Table 4
Mean Sex Quality Composite Scores for Successfully Treated Couples

Treatment	Pre	Post	Follow-up
Males			
Standard	23.8 ^a	42.4 ^a	40.8 ^b
Phone contact	25.2 ^a	38.5 ^a	30.1 ^d
Females			
Standard	25.8 ^a	43.1 ^a	37.8 ^a
Phone contact	28.7 ^a	47.7 ^a	34.7 ^d

Note. Because of the small n , follow-up data were not included in analyses of variance.

^a $n = 6$.

^b $n = 4$.

^c $n = 5$.

^d $n = 3$.

latory control, satisfaction with the sexual relationship, and response to sexual advances by mate. The index for females consisted of the same seven items plus an item regarding the frequency of orgasm in intercourse. Responses to each question were assigned numerical equivalents on a 9-point scale (0-8), with equal intervals between the two extremes. Larger numbers reflected higher quality of the sexual relationship. Thus, the maximum possible score for males on this index was 56, for females, it was 64. Item intercorrelations for the sex quality composite at pretest are available on request from the author (only 3 of 21 item intercorrelations for males and only 3 of 28 for females are significant). Thus, the items contributing to the composite mean are largely independent.

eight couples were also examined. The pattern was the same as with ejaculatory latency—improvement with treatment, followed by a moderate deterioration by the time of follow-up, both for males and for females. Means for males were 26.36 at pretest, 42.57 at posttest, and 36.18 at follow-up; means for females were 28.50 at pretest, 45.50 at posttest, and 36.75 at follow-up. t tests for paired observations indicated that sex quality scores dropped significantly between posttreatment and follow-up assessments for both sexes: For males, $t(6) = 2.33$, $p < .05$; for females, $t(7) = 3.06$, $p < .01$. Despite this decrease, the quality of sex at follow-up remained significantly greater than the quality of sex before treatment for both sexes: For males, $t(6) = 2.80$, $p < .025$; for females, $t(7) = 3.53$, $p < .005$. It was also found that the posttreatment sex quality composite for males was highly predictive of follow-up ejaculatory latency estimates, $r(5) = .87$, $p < .01$, whereas the composite for females was not ($r = -.10$).

Mechanism of Successful Treatment

To examine the mechanism by which treatment for premature ejaculation works, couples at posttreatment were asked to time their ejaculatory latencies first as intercourse normally occurred and then without using any squeezes or pauses; 10 couples provided these data. Mean latency was 10 min 33 sec as intercourse normally occurred and 4 min 21 sec with no squeezes or pauses, $t(9) = 2.90$, $p < .01$. Mean posttreatment latency without squeezes or pauses was significantly greater than mean pretreatment latency, which was 1 min 30 sec for these 10 couples, $t(9) = 3.82$, $p < .005$. Thus, although treatment was most effective when couples continued to use the squeeze or pause, there was also a significant effect of treatment on simple ejaculatory latency when squeezes and pauses were not used.

Discussion

The results of this study indicate, in a population with fairly stable relationships and long histories of premature ejaculation, that couples can successfully treat themselves

using a written instructional guide *if they maintain minimal contact with a therapist*. In this instance, minimal therapist contact was by telephone, averaged 6 minutes per week, and generally was not specifically therapeutic in nature. Rather, phone contacts served primarily to check on, encourage, and congratulate treatment progress. Without the non-specific therapeutic effects of ongoing contact with a therapist, couples failed to complete treatment successfully, generally because of ceasing to follow the treatment plan. These results were consistent across a variety of measures, including timed ejaculatory latency, estimated latency, and the sex quality composite. There did not seem to be indications of concomitant improvement in the general marital relationship.

The brevity and nature of phone contacts with minimal therapist contact couples suggest that the treatment exercises outlined by the Zeiss and Zeiss (1978) manual are sufficient for successful treatment when followed. However, evidence from the no-contact condition indicates that an external source of encouragement and motivation is probably necessary in order for couples to follow through with treatment exercises. Graduate student and relatively inexperienced paraprofessional therapists filled the therapist role in this study; the same function could probably be fulfilled by others with minimal training in the treatment of sexual dysfunction. These might include physicians, psychologists, mental health paraprofessionals, or the clergy.

The success of treatment with minimal therapist contact suggests that the cost of a standard, in-clinic therapist-administered treatment for premature ejaculation may no longer be justifiable for those couples with well-defined and simple premature ejaculation difficulties. Rather, couples could be offered the use of the self-directed treatment program in conjunction with minimal contact with a therapist. In this framework, intensive professional counseling could be reserved for those couples who fail to succeed with the minimal contact approach or for couples whose premature ejaculation difficulties are compounded by other clinical problems.

A recent review of the behavioral self-help

literature (Glasgow & Rosen, 1978) indicates that dropout problems similar to those found in this study have been noted with self-directed treatments in other areas such as fear reduction (Clark, 1973; Marshall, Presse, & Andrews, 1976; Phillips, Johnson, & Geyer, 1972; Rosen, Glasgow, & Barrera, 1976), weight reduction (Hanson, Borden, Hall, & Hall, 1976; Mahoney, Moura, & Wade, 1973), and study skills training (Beneke & Harris, 1972; Harris & Ream, 1972). Many of these studies noted dropout problems with minimal therapist contact applications, as well as with strictly self-administered treatment applications. In the current study, the dropout problem was restricted to the self-administered condition but persisted even with the existence of monetary contingency deposits.

Previous work on the treatment of premature ejaculation has not specified the mechanism by which treatment is effective, although Levine (1976) has reported that unlimited control is often not developed. An analysis of posttreatment data indicated that greatest improvement in ejaculatory control occurred when couples continued to use the squeeze or pause to delay ejaculation, but significant improvement in latency to ejaculation also occurred when couples used neither technique to lengthen intercourse. This finding concurs with Levine's conclusions.

By the criteria used to define success, half of the successfully treated couples for whom there were follow-up data could no longer be classified as successfully treated at follow-up. The reasons for this decrease in latency and general quality of sex are not clear, although it may be that there is a glow of success that tends to deteriorate in the months following treatment for sexual dysfunction, or couples may have simply decreased their use of the squeeze or pause after completing treatment. It should be noted that although estimated latencies and the sex quality composite both decreased following completion of treatment, couples remained significantly improved on these variables at follow-up, compared to pretreatment assessment.

Also of interest is the finding that post-treatment ejaculatory latency is predictive of ejaculatory latency at follow-up. This suggests that even though there was a general

decrease in latencies from posttreatment to follow-up, the decrease occurred across most couples, resulting in similar ranking of improvement at follow-up. Even more powerfully predictive of ejaculatory latency at follow-up was the posttreatment sex quality composite for men. The composite for women was not predictive of follow-up results. This indicates that improvement in latency tends to maintain when the male partner is satisfied with the sexual relationship; if he is less satisfied with the sexual relationship, improvements in his ejaculatory latency fail to maintain.

This finding may shed some light on a factor that has perplexed sex therapists at this clinic for years. Many couples who have been successfully treated for sexual dysfunction have improved on their target problem during treatment, but after the termination of treatment, the frequency of sexual activity tends to revert to very low pretreatment levels, in spite of reports that improvement in the target areas has maintained. That is, the man retains his newly learned ejaculatory control or the woman retains her capacity for orgasm (LoPiccolo, Note 1). This contradiction is perplexing because of the presumed reinforcement value of sexual activity in general and orgasm in particular.

Although couples are referred with specific dysfunctions, and although we as behavior therapists eagerly label and treat their dysfunctions, it may be that resolution of the specific dysfunctions does not adequately resolve these couples' unspecified needs for a general improvement of the sexual relationship. Thus, in addition to resolving specific dysfunctions, therapy should probably concern itself with all aspects of the sexual relationship. If the general relationship does not improve along with the target behavior, improvements in that target behavior will not necessarily maintain.

Therapeutic Effectiveness of Setting and Monitoring Goals

Russell R. Hart

Copper Mountain Mental Health Center, Salt Lake City, Utah

This study investigated the therapeutic effects of goal-setting strategies on patients whose behaviors were disintegrating but not fragmented or disoriented. Two techniques of goal setting were introduced into the therapeutic interaction to effect greater beneficial changes in patient attainment of goals: (a) collaboration of patients, therapists, and "collaterals" (other persons significant to the patient, such as spouse or probation officer) on 3-month treatment goals and (b) weekly monitoring with structured feedback. Sixteen outpatients were randomly assigned to a treatment group for which the Behavioral Monitoring Progress Record was used. The Behavioral Monitoring Progress Record is a method in which the patient and therapist collaborate in setting and monitoring weekly therapeutic goals. Sixteen other outpatients were randomly assigned to the same individual therapy but without weekly goal setting or monitoring. Collateral persons and behavioral criteria were used at intake for collecting information in each problem area and were used at follow-up to validate the patient's self-report. A score was used as an index of change. All patients improved from the time of intake to the time of the follow-up interview, eight individual therapy sessions later. There was greater success in the attainment of goals for patients using the Behavioral Monitoring Progress Record than for patients in the group not using this format.

Because of the increasing emphasis on accountability within community mental health centers, Kiresuk (1973) has proposed a method for evaluating treatment effectiveness in psychotherapy using goal attainment scaling procedures. Goal attainment scaling is a process in which therapeutic goals are set for, by, or with the subject. The possible levels of predicted attainment of these goals are scaled from the least favorable to the most favorable outcomes in behavioral terms.

Although the purpose of Kiresuk's work was to develop a method of quantifying behavioral change, the process of setting and scaling goals appeared to have potential as a therapeutic procedure.

The major objective in this study was to evaluate the therapeutic effectiveness of setting goals in behavioral terms while monitoring the subject's progress in attaining these

goals. To accomplish this objective, the answer to two questions were sought: Did behavior change occur from intake to follow-up evaluation? and Was there a difference in behavior change between the monitored and control groups?

Method

The subjects were 32 adult patients at a community mental health center whose mental functioning was not sufficiently impaired to require hospitalization. The decision to include a patient depended on the answers to two essential questions: (a) Is short-term (3 months) individual psychotherapy clinically appropriate treatment for the patient? and (b) Is the patient capable of participating meaningfully and responsibly in a therapy program?

Instruments

The instruments used in this study were the Goal Attainment Scale (GAS; Kiresuk & Sherman, 1968), the Behavioral Monitoring Progress Record, and the Follow-up Interview Schedule.

NOTES:

Figure 1. Behavioral Monitoring Progress Record.

The Behavioral Monitoring Progress Record (BMPR). The BMPR was designed to increase the therapeutic movement of the patient by having patients set goals and report on their progress at each therapy session (see Figure 1). A predicted 4-week goal was set with the patient, and successive weekly goal approximations were also determined. Within each problem area, a weekly goal and method of attainment was specified. These methods were carefully defined behavioral "assignments." The patient and therapist jointly assessed the degree of attainment of each goal. For example, unassertiveness might be a problem area. The 4-week goal might be to be assertive on seven occasions during the week; the method for the first weekly goal might be to stand up for one's rights once in a restaurant, once with the boss, and once with one's spouse. Hence, a most important emphasis was on setting weekly goals that were observable, definable, and measurable and methods that were structured in a step-by-step, reasonable,

and realistic manner and collaborated and monitored weekly by both patient and therapist.

The Follow-up Interview Schedule. The GAS Follow-up Interview Schedule (adapted from Garwick, 1974a), is a structured interview that allows for quantitative assessment of patient functioning within the problem areas for which goals have been set.

Patients who were selected as subjects in the study were asked to complete the "guide to goals" (Garwick, 1974b). Then an "intake history" was prepared on the basis of two interview sessions.

At a third session, the patient and an experienced clinician "scaler," trained in goal attainment scaling, collaboratively prepared a follow-up guide. The scaler interviewed "collateral" persons significant to the patient's problem areas. The scaler initially interviewed the collateral within each problem area that the patient presented and in a separate interview with the patient collaboratively constructed the goal attainment follow-up guide.

The construction of the follow-up guide consisted of setting treatment goals and predicting five levels of goal attainment with an "expected" level of attainment by the eighth therapy session. The patients were then randomly assigned to the two treatment groups and to the psychotherapists for individual counseling.

The monitored group received individual therapy and weekly goals using a structured feedback technique (BMPR). The nonmonitored group received individual therapy *without* setting goals.

The Follow-up Interview Schedule ratings were completed after eight therapy sessions within a 3-month period by one of four master's level psychiatric nurses. Separate posttest scores were recorded for both patients and collaterals.

The collateral person was a source of external validation of the patient's self-report. Validation included identification and definition of the patient's problems at intake (pretest score) and input as to the level of functioning on the attainment level of the follow-up guide at the follow-up evaluation (collateral posttest score).

Results

The purpose of this study was to determine what changes, if any, occurred from the time of intake to the time of follow-up between two treatment groups, only one of which used a structured feedback technique for collaboration and monitoring goals.

The following hypotheses were used to examine the therapeutic effectiveness of goal attainment scaling:

Hypothesis 1. There is no difference in the mean Goal Attainment scores for the pretest, the posttest, and the collateral posttest.

Hypothesis 2. There is no difference in the means on the goal attainment scores of the treatment and control groups.

Hypothesis 3. There is no interaction between testings and treatment groups on the Goal Attainment scores.

To test these hypotheses, a two-way analysis of variance (see Table 1) with repeated measures on one factor (Winer, 1962) was used.

Mean Total Pretest Versus Patient Posttest Versus Collateral Posttest Goal Attainment Scores

The mean totals of the patient (49.16) and collateral (50.15) after therapy were more than twice as great as the mean total pretherapy score (23.29). As shown in Table 1, a significant treatment effect was found for pretherapy versus patient posttherapy versus collateral posttherapy Goal Attainment scores ($F = 327.66, p = .01$).

Mean Total Control Group Versus Monitored Group Attainment Scores

The mean total Goal Attainment score for the monitored group (45.73) was much greater than the mean total Goal Attainment score for the control group (36.01). The monitored patients attained significantly higher scores than the control patients ($F = 32.43, p = .01$).

Interaction

Control Group Versus Monitored Group

Both the patient (56.82) and collateral (57.72) posttherapy scores of the monitored

Table 1

Between subjects	4,370.05	31		
Monitored vs. control (A)	2,270.20	1	2,270.20	32.43*
Subjects within groups	2,099.84	30	70.00	
Within subjects	17,656.01	64		
Pre, post, and collateral observations (B)	14,847.10	2	7,423.55	327.66*
A \times B	1,449.53	2	724.80	31.99*
B \times subjects within groups	1,359.38	60	22.70	

Note. $N = 32$.

* $p < .01$.

Table 2
Mean Initial and Follow-Up Goal Attainment Scores

Item	<i>M</i> initial scores (all scales)	<i>M</i> score based on patient report at 3 months	<i>M</i> score based on ratings by collaterals at 3 months	Total (between groups)
Initial follow-up guide only (control group)	23.92	41.51	42.59	36.01
Weekly goals review plus initial follow-up guide (monitored group)	22.66	56.82	57.72	45.73
Total (within groups)	23.29	49.16	50.15	40.87

group were significantly higher than both the patient (41.51) and collateral (42.59) posttherapy scores of the control group ($F = 31.99, p = .01$).

Table 2 represents the mean Goal Attainment scores at pretherapy, patient posttherapy, and collateral posttherapy interactions. There were differences between testings and treatment groups on the Goal Attainment scores. Patients in the monitored group had significantly higher mean scores in both posttestings on patient reports and collateral ratings than did patients in the control group, whereas mean initial scores for both treatment groups were similar.

Discussion

The significant change in the mean Goal Attainment scores from pretherapy to posttherapy suggests that positive therapeutic changes occurred during treatment. Undesirable behaviors decreased, and desirable behaviors increased. The treatment goals that were selected and the levels of outcome that were achieved demonstrate that reasonable and realistic goals were set and accomplished with these patients.

The significant difference between the mean Goal Attainment scores for patients in the monitored group and the control group suggests that greater beneficial changes in patient attainment of goals were effected in the monitored group using a structured format of patient-therapist collaboration on weekly goals than when the guide to goals was used without weekly goal setting.

It appears that goal-setting strategies, when used in a procedural format, allow the

patient and therapist to be more responsible and accountable in assuring the process of appraisal and improvement of the quality. Behavior changed gradually and improved when the patient and therapist had the feedback of the established goals of the prior week and methods to accomplish these goals. Feedback provided both the patient and therapist with information on treatment decision and outcome and provided alternative approaches for future goal attainment strategy.

These results indicate that the goal attainment model with periodic monitoring may be useful in the therapeutic process to collect information, as an aid in organizing and recording the process of therapy, to design treatment for outpatients, as an outcome effectiveness measure, to evaluate therapeutic progress, and to provide new data for setting additional therapeutic goals.

An Observational Approach to the Assessment of Anxiety in Young Children

Blair Glennon
Harvard University

John R. Weisz
University of North Carolina at Chapel Hill

Clinical research on anxiety has long relied on assessment techniques that may be inappropriate with young children (e.g., self-report inventories). The present article describes an alternative to such techniques—a scale using observational methodology. To assess the reliability and validity of this instrument, the Preschool Observational Scale of Anxiety (POSA), preschoolers were observed and scored on the scale during two test sessions. Session 1, with mothers absent, was expected to provoke relatively high anxiety; Session 2, with mothers present, was expected to provoke minimal anxiety. Total POSA scores assigned by two independent judges correlated .78 ($p < .001$), with highly significant interjudge correlations for most of the scale items. Regarding the validity of the instrument, it was found that (a) POSA scores were significantly correlated with teachers' and parents' inventory ratings of children's anxiety (all $ps < .01$), and (b) children's POSA scores were significantly higher in Session 1 than Session 2 ($p < .01$). The findings suggest that the POSA may provide a means of assessing situationally induced anxiety in children who are too young to accurately report their internal states.

Anxiety has long been a topic of central importance in clinical research and practice. Achenbach (1974) noted that among personality traits emerging from trait theories, "anxiety is perhaps the most frequently inferred and measured (p. 574)"; yet, demonstrably valid and reliable measurement of anxiety has been difficult to achieve, particularly among children. Especially acute is the need for accurate measures that can be used to assess specific situational effects on anxiety states in children (see Spielberger et al., 1972). Although many investigators recognize the need for such measures, particularly in research with children who are too young to

accurately report their own internal states, most researchers also recognize the difficulties that inhere in applying previous anxiety assessment techniques to children.

Historically, the principal methods for measuring anxiety have been physiological measurements, projective techniques, self-reports, and behavior ratings by observers. Through direct gauging of autonomic activity, physiological measures bypass the problems of subjective judgments. However, agreement among physiological measures is frequently poor, since people have different styles of autonomic responding (Phillips, Martin, & Meyers, 1972), and the physiological instruments may tap emotions such as anger or joy rather than anxiety (Lazarus, 1966). Furthermore, the unusual instruments used for physiological measures may distract subjects and make naturalistic observations difficult, particularly when the subjects are children.

Projective techniques have also been used to obtain ratings of generalized anxiety (McReynolds, 1968), but most projective techniques require individual administration as well as substantial time and expertise on the

The study was supported in part by a research grant from the College of Human Ecology, Cornell University.

The authors are grateful to Barbara Cesario, John Doris, Laura Harrison, Robert Loheyde, Linda Mack, and the staff, parents, and children of the Cornell Nursery School for their assistance in the conduct of this study.

part of the examiner, thus limiting their usefulness. Furthermore, McReynolds (1968) has reported that projective techniques "are generally found to be unrelated to inventory essays of anxiety" (p. 258); and Achenbach (1974), after reviewing the massive literature on projective techniques, has concluded that "there is little evidence for the reliability or validity of most of the interpretations made from them" (p. 604).

Three main types of self-reports have been used in assessing anxiety. First, direct self-ratings involve asking subjects specifically how anxious or nervous they feel. McReynolds (1968) has suggested that such self-ratings are most useful for measuring current levels of anxiety or changes in anxiety from one situation to another. A second type of self-report is the Adjective Check List, on which subjects indicate which of several adjectives (e.g., "jittery") best characterize their mood. Adjective Check Lists have been used to assess either current anxiety level or characteristic anxiety (McReynolds, 1968). The third type of self-report is the inventory method, with questionnaires designed to determine how subjects feel in a variety of situations. This method is usually aimed at assessing characteristic rather than current anxiety level. Inventories may focus on generalized anxiety (i.e., across a wide variety of situations) or anxiety related to particular types of situations (such as separations). Several investigators have noted drawbacks of the various self-report methods (see Spielberger, 1972); however, probably the most important drawback in the present context is that such methods assume both the ability and the willingness of subjects to correctly describe their own feelings. The first assumption is clearly tenuous with young children. And, with regard to the second assumption, there is evidence that many children give inaccurate reports about their anxiety due to defensiveness or social pressures (Sarason, Davidson, Lighthall, Waite, & Ruebush, 1960). Consequently, Sarason (1966) has stated that "the verbal response to our [children's self-report anxiety] scales may be telling us more about the self than the affect" (p. 79).

Behavior ratings of anxiety by observers may involve global, subjective judgments

about the subjects' apparent nervousness or ratings on many specific, concrete behaviors thought to indicate anxiety (e.g., stuttering). Such approaches appear to offer distinct advantages relative to those discussed above (see Spielberger et al., 1972). For instance, unlike physiological measures, observers' behavior ratings can be made unobtrusively; unlike projective techniques, they do not necessarily require trained clinicians; and unlike self-report measures, they do not rest on tenuous assumptions about the abilities and attitudes of the subjects. In addition, behavioral observations may be particularly useful with children, since they appear to disguise expression of their feelings less effectively than adults (Sarason, 1966).

The observers for the behavior rating scales of children's anxiety are sometimes teachers or parents, with the scales including items relevant to school or family situations (e.g., cries at bedtime). However, these particular scales entail a risk of distortion due to the parent's or teacher's lack of care or objectivity in observing, or to their bias or defensiveness about reporting on a child whom they know personally (Sarason et al., 1960). The observers for the behavior rating scales, however, may be trained observers (see Buss, Wiener, Durkee, & Baer, 1955), and the scales may comprise behaviors indicative of anxiety across situations, thus being more widely applicable and less subject to distortion by observers. The latter type of behavior rating scale would, in principle, permit detection of subtle relationships between specific events and ensuing anxiety in a way that satisfies methodological requirements and is developmentally appropriate as well (see Weisz, 1978).

It is true that different individuals may reveal their anxiety through different behaviors; also, different observers may have difficulty achieving high agreement in their behavior observations. But these problems of behavior ratings should be surmountable. Clearly defining the behaviors to be observed and increasing the training time of observers should reduce problems of low interrater agreement. And total frequency scores on rating scales including the gamut of behaviors suggestive of anxiety should give good indi-

cations of the relative anxiety of individuals with widely varying anxiety manifestations.

The most accurate behavior rating scale would require observers who are able to concentrate fully on the occurrence of the target behaviors and to record the occurrence of these behaviors for later frequency analysis. It should be noted that in the typical clinical interview situation, the clinician would not be able to meet these requirements. However, a second observer could independently record the indicators in clinical situations in which precise anxiety measurements are desired, or the clinicians themselves could use the indicators of behavior rating scales as an aid in making less exact, more global ratings of the client's anxiety. In the latter case, the clinicians would not be using the scale in the prescribed way but would probably add objectivity to their observations by reference to it.

In short, behavior observation measures of anxiety seem to have clear advantages over other types of anxiety measures and relatively minor drawbacks. But despite the potential usefulness of such measures, we have found little systematic research on behavior indicators of anxiety in children. In fact, there appears to be no carefully validated behavior rating scale for anxiety in children. Perhaps the closest approach is that of Grossman (1968), who used observer ratings of anxiety with 6-year-olds. However, his scale consisted of a mixture of specific objectively observable behaviors (e.g., nail-biting) and general indicators requiring subjective inference (e.g., "reactions suggesting that the child was frightened"); as described by the author, the scale appeared to contain only six items, thus showing limited sensitivity to the range of behaviors through which children may display anxiety. Validity data consisted of only two nonsignificant correlation coefficients relating the behavior scale to the General Anxiety Scale for Children (Sarason, Davidson, Lighthall, & Waite, 1958), and to our knowledge, no independent studies have been done to support the use of the scale as an anxiety measure. Melamed and Siegel (1975) used their Observer Rating Scale of Anxiety in a study on the reduction of anxiety through filmed modeling in 4- to 12-year-old

children facing surgery. Again, only very limited validity data on this scale are available. Also, only four items of the scale were published, and these represent an exceedingly modest sampling of the possible behavioral manifestations of anxiety.

In the present study, a much more detailed list of behavior items was assembled by means of a systematic search of the anxiety literature. This list was used to form the Preschool Observation Scale of Anxiety (POSA). The interobserver reliability of the POSA was assessed by two independent judges. The validity of the scale was determined (a) through assessment of its relation to three independent inventory measures of anxiety and (b) through an experimental manipulation of stressors. Significant positive relations between the POSA scores and the inventory scores were anticipated, but these relations were expected to be modest, since (a) the inventory measures and the POSA were designed to assess somewhat different aspects of anxiety, and (b) the inventory measures relied on parents' and teachers' judgments, whereas the POSA involved relatively objective observations by trained observers. The experimental manipulation involved a contrast between an initial mother-absent condition and a subsequent mother-present condition. Because the format and experimental procedure would be more familiar to the children in the second session, and because mothers would be present, it was predicted that children would show lower levels of anxiety in Session 2 than in Session 1, and thus score lower on the POSA.

Method

Subjects

The 36 Cornell University Nursery School children who formed the sample ranged in age from 32 to 59 months ($M = 47$ months; $SD = 7.7$ months). Mean Hollingshead (Note 1) socioeconomic status (SES) was 1.47 (1 = highest; 7 = lowest; $SD = .94$). There were 21 girls and 15 boys.

Procedure

The Preschool Observation Scale of Anxiety. The first step in devising the scale was a systematic search of the *Education Index* (1929-1976), *Psychological Abstracts* (1927-1976), *Resources in Education/Re-*

search in Education [1966 (year or origin) to 1976], and *Current Index to Journals in Education* [1969 (year of origin) to 1976], for studies using or mentioning behavioral indicators of anxiety in children or adults. Next, three child-clinical psychologists examined a list of items based on the literature search to suggest additions, to make minor modifications, and to give their final approval to the scale. Some behavior indicators suggested by the literature or the clinicians (e.g., hand perspiration) were not included in the final scale because pilot testing indicated that they were too difficult to observe accurately and reliably. Table 1 includes a description of each behavioral indicator of the final POSA, along with a reference to the article(s) supporting the use of each indicator in the scale.

Parent and teacher questionnaires: Independent anxiety measures. Several independent measures of anxiety were obtained for the purpose of validating the POSA. One was a questionnaire, the Parent Anxiety Rating Scale (Doris, McIntyre, Kelsey, & Lehman, 1971), completed by each child's parents and comprised of six questions about the child's separation anxiety (PARSEP) and 19 questions about the child's general anxiety (PARGEN). Two weeks before school began, this questionnaire was sent to the children's parents, who completed it by the beginning of the nursery school year. A second independent measure of anxiety was the Teachers' Separation Anxiety Scale (TSAS; Doris et al., 1971), comprised of 11 items about the child's reaction to separation from his/her mother or father when left at the nursery school at the beginning of the school day. One of two teachers (one for each of two nursery school sessions) rated the child on each of the first 10 consecutive days of the child's attendance at nursery school for the year. Ratings were made at the end of each school day and pertained to the period from the child's arrival at the nursery school with parent to the parent's departure. If the child was not delivered to the nursery school by his/her parent, the child was not rated that day, and his/her TSAS score was prorated.

Experimental manipulation of anxiety. In addition to obtaining questionnaire scores of the children's anxiety, we used a manipulation designed to create differing levels of anxiety in two experimental sessions, both involving cognitive tests. The first session was expected to be more anxiety arousing, since it involved an unfamiliar adult who individually tested each child in an unfamiliar setting during one of the first few days of the nursery school year. In contrast, the second session occurred approximately 2 weeks following the first session, after the children had had a chance to settle in to their new surroundings; furthermore, the child's mother was present at the second session, along with the same examiner who had tested the child at the first session. Finally, the children were given the same three tests in the second session that they had already taken in the first session.

Tests were given because it was felt that an evaluative atmosphere would make the experimental

situation more anxiety arousing, especially in the first session when the materials would be unfamiliar. Also, performance on the cognitive tests by the high-anxious children compared to the low-anxious children was of interest, since existing evidence is in conflict over this question. Some evidence suggests that high anxiety should interfere with test performance, especially when the tests are fairly difficult ones for the subjects (e.g., Feldhusen & Klausmeier, 1962; Tamaroff, 1976; Young & Brown, 1973). However, other evidence (e.g., Denny, 1966; Hodges & Durham, 1972; Katahn, 1966; Spielberger, 1966) suggests that anxiety may have facilitating effects on performance for children of higher socioeconomic and intellectual levels. (See other conflicting evidence in Fischer & Awrey, 1973; Mazzei & Goulet, 1969.) Since, according to the evidence, anxiety might lead to performance enhancement in some children and performance decrements in other children, no prediction was advanced regarding the relation between anxiety and task performance in the present study. However, the relation between task performance and anxiety scores was reported in an effort to shed light on the controversy just described.

Global anxiety self-ratings and ratings by the examiner. In the Introduction to this article, we emphasized the disadvantage of both self-reports by children and global (and thus subjective) ratings by adults. To determine whether our negative assessment was correct, we included two such measures in the present study, so that their effectiveness might be contrasted with that of the more specific and presumably more objective POSA. At the end of each of the two testing sessions, the examiner rated the child's general anxiety level during the session on a scale of 1 to 6. Also, a teacher asked each child to choose one of six pictures depicting progressively more fearful facial expressions to show how anxious the child felt during the testing session. The teacher rather than the examiner asked this question, since it was felt that the children would be more candid about their feelings with their teacher. The wording of the question was the following:

These pictures show a picture of a child who is more and more scared as you go from this top picture to the bottom picture here [point]. You see, up here the child is not scared at all [point]; here [second picture from top] the child is a little more scared but still pretty happy; here [third from top], he's getting more scared; and here [bottom], very, very scared. Which picture would show how scared you felt when you went downstairs to the testing room with that lady? One of these up here where the child isn't scared at all, or one of the bottom ones showing a child who is more and more scared?

The observation periods. At the beginning of the first session, the examiner, a 26-year-old experienced female teacher, approached each child individually in the nursery school and told the child

Table 1

Items of the Preschool Observation Scale of Anxiety and Interrater Agreement During the First 10 Minutes of the First Session

Item	Range of frequency	Interrater reliability*	Concordance 1	Concordance 2
1. Physical complaint: Child says he or she has a headache, stomachache, or has to go to the bathroom (B,C,D,E,G,K,Q)	0-0	nc ^b	nc	nc
2. Desire to leave: Child says he or she wants to leave the testing room or makes excuses about why he or she must leave; desire or "need" to leave must be explicit (D,E,P,Q).	0-5	.99*	.99	.46
3. Expression of fear or worry: Child complains about being afraid of or worried about something; must use the word "afraid," "scared," "worried," or a synonym (F).	0-0	nc	nc	nc
4. Cry: Tears should be visible (G,I,K,P,Q).	0-2	nc	nc	nc
5. Scream (P).	0-0	nc	nc	nc
6. Whine or whimper (G,P).	0-2	.69*	.97	.17
7. Trembling voice (F,G,I,M).	0-1	nc	nc	nc
8. Stutter (A,F,G,H,M,O).	0-0	nc	nc	nc
9. Whisper: Child speaks softly, without vocal cords; should not be a playful whisper (E,G).	0-11	.67*	.87	.39
10. Silence to one question in the interval (E).	0-3	.74*	.98	.50
11. Silence to more than one question in the interval (E).	0-5	.82*	.95	.22
12. Nail-biting: Child actually bites his or her nails in the testing room (F,G,I).	0-3	.83*	.98	.46
13. Lip-licking: Tongue should be visible (G).	0-13	.94*	.89	.63
14. Fingers touching mouth area: not counted if bites nails while touching mouth.	0-17	.96*	.91	.79
15. Sucking or chewing object: not fingernails (G,P).	0-1	.47*	.99	.33

Note. Letters in parentheses following each item description refer to studies suggesting that item as an anxiety indicator. The following code was used: A: Boland (1953); B: Buss, Wiener, Durkee, and Baer (1955); C: Cowen, Zax, Klein, Izzo, and Trost (1965); D: Endler, Hunt, and Rosenstein (1962); E: Fink (1956); F: Grossman (1968); G: Insel and Spencer (1972); H: Kasl and Mahl (1965); I: McReynolds (1965); J: Melamed and Siegel (1975); K: Miller, Barrett, Hampe, and Noble (1971); L: Nottelman (1975); M: Paul (1966); N: Raskin (1962); O: Santostefano (1960); P: Tamaroff (1976); Q: Wolff (1969). Items 14 and 16 were suggested by our clinician consultants. The range of frequency column gives the lowest score obtained by any subject and the highest score obtained by any subject. The interrater reliability column gives the correlation coefficients for the Pearson correlations between the scores of the two observers. The Concordance 2 column gives the interrater agreements on the occurrence of indicators in pairs of adjoining intervals (the number of agreements divided by the sum of agreements plus disagreements). The Concordance 1 column gives the interrater agreement on both the occurrence and nonoccurrence of indicators in pairs of adjoining intervals (again, the number of agreements by the sum of agreements plus disagreements).

^a n = 33 for interrater reliability and concordance calculations.

^b nc = not calculated due to infrequent occurrence (i.e., no children or only one child had nonzero scores on the indicator).

^c Based on only two children with nonzero scores.

* $p < .001$.

that she wanted him or her to go with her to another room "to do some tests."¹

The testing room was 5.7 m × 3.5 m, with one-way mirrors on top of its four walls and a microphone about 30 cm above the child's head for transmitting sounds from the testing room to the observation areas. A male and a female observer, both in their early 30s, sat behind the one-way mirrors at a distance of about 1.2 m from the child. The observers sat around a corner from each other, and were separated by about 1.5 m and a partition. Each observer spoke softly into a tape recorder each time he or she observed the child emit one of the 30 behavioral indicators. The two observers could not hear each other speaking. Also, the observers were blind to the independent anxiety ratings of the children whom they observed and to the fact that lower anxiety ratings were expected for the second session in comparison to the first session.

A standard time-sampling procedure involving 30-sec intervals was used. A Davis Scientific Instruments General Purpose Time Interval Generator (Model B501) emitted to each observer a beep and a red-light flash at the 30-sec intervals. Aside from

preventing observers from habituating to the behavioral indicators, this procedure was used to aid data analysis: Behaviors were given a score of 1 for each interval in which they occurred.

During the testing session, the examiner gave each child the three tests (Digits, Blocks, and Sentences) in standard form and in as neutral a manner as possible. The examiner was instructed to try to keep the children in the testing room for at least 10 minutes. The Digits test was taken from the Illinois Test of Psycholinguistic Abilities (Kirk, McCarthy, & Kirk, 1968) and involved repeating a series of orally presented digits from memory. Sentences were taken from Tamaroff's (1976) adaptation of the Sentences subtest of the Wechsler Preschool and Primary Scale of Intelligence (Wechsler, 1967). This test requires the child to repeat increasingly complex orally presented sentences from memory. Finally, Blocks was taken from Tamaroff's (1976)

¹ Two children refused to do any tests in the first session, and one refused to do any in the second session.

adaptation of the Block Construction Test of the Yale Scale of Child Development. It requires the child to copy visible block constructions with separate blocks, and it is timed.

In the second testing session, the same procedure was followed, except for two variations. First, the child was accompanied to the testing room by his or her mother as well as by the examiner, and the mother sat unobtrusively reading a magazine in the corner of the testing room during the session. Second, only the female observer was behind the one-way mirrors, since the second observer was used just during the first session to obtain interrater reliabilities. Of the 36 children in Session 1, 32 participated in Session 2. One child refused, and the parents of 3 children were unable to participate. Technical difficulties with recording equipment further reduced the sample (for whom complete data on both sessions were available) to 29.

Training for the observers. Both observers spent 2-3 hours memorizing the behavioral indicators and 6 hours in observation-training sessions. In training, the observers watched videotapes of three children being tested as other children would be tested in the actual experiment. Training also involved pilot observations of three children in the actual setting and conditions of the experiment. Finally, the observers spent approximately 2 hours discussing disagreements in their observations and ways to achieve better consensus. The detailed description of the items of the POSA given in Table 1 includes all of the details that the observers devised in order to maximize agreement.

Results

Scores for all subjects on the POSA were calculated by using the number of 30-sec intervals in which a given indicator occurred during the first 10 min (20 intervals) of the sessions. The examiner had been instructed to try to keep each subject in the testing room and working for a full 10 min; thus, a 10-min interval was chosen as the target time, in part, because of concern that the experimenter's behavior might have changed significantly after the 10-min period had expired.²

Interrater Reliabilities

To assess interrater reliability, Pearson correlations between the ratings of the two observers were calculated using the Session 1 scores for each indicator separately and for the sum of all 30 indicators (see Table 1 third column from the right). The most im-

portant correlation coefficient, that for the 30 indicators together, was .78 ($p < .001$). The intraclass correlation was .77 ($p < .001$).

Even though the preceding analysis answered the central question about reliability of overall POSA and individual indicator scores, we also sought to learn the level of specificity at which observer agreement took place. Toward this end we used a demanding procedure designed to gauge the degree of concordance between observers *within* observation intervals. The procedure involved grouping every 2 adjoining intervals (resulting in 19 interval groups) and counting how often the observers agreed or disagreed as to whether an indicator occurred within each interval group. Adjoining rather than single intervals were used for this agreement measure, since the observers sometimes reported the same behavior at slightly different times so that the interval cutoff occurred between their reports. Using this method of measurement, a quotient of concordance was calculated by dividing the number of agreements between the observers by the number of their "agreements" plus "disagreements" for each indicator separately and for the total of all 30 indicators. Table 1 (last two columns) shows the results of these calculations (a) when agreements between observers that a given indicator did *not* occur were included in the "agreement" score and (b) when such negative agreements were excluded from the agreement score. Considering the rigorous nature of the procedure (particularly b above), the percentages shown in Table 1 represent rather substantial agreement between observers at the level of brief observation intervals.

² The alternate scoring method of dividing the frequency of intervals in which each indicator occurred during the total session by the number of intervals in the total session would have posed an additional problem, in that fatigue and familiarity could have affected the scores of children having longer sessions. Unfortunately, using the 10-minute cutoff, all subjects were not engaged in the same activities during the target time, but this seemed to be a less significant consideration than those noted above.

Table 2
Correlations Among Anxiety Measures and Test Scores

	2	3	4	5	6	7	8	Sentences

3. PARGEN			.22	-.18	.07	.03	.05	.05
4. TSAS				-.05	.19	-.07	.07	-.18
5. Self-rating					.14	-.45**	-.35*	-.24
6. Examiner rating						-.24*	-.10	-.13
7. Blocks							.42**	.62***
8. Digits								.72***

Note. POSA = Preschool Observation Scale of Anxiety; PARSEP = questions about the child's separation anxiety; PARGEN = questions about the child's general anxiety; TSAS = Teachers' Separation Anxiety Scale.

* $p < .05$.

** $p < .01$.

*** $p < .001$.

Correlations With Independent Measures of Anxiety

As an initial step in assessing the validity of the POSA, the correlations of the POSA with the PARSEP, PARGEN, and TSAS were calculated using data from the first session (since correlations with data of the second session would have been less meaningful due to the mothers' presence). As Table 2 indicates, all three correlations were significant. Other correlations noted in the table are also of interest. Note that the self-rating and examiner ratings were not correlated with one another or with POSA, PARSEP, PARGEN, or TSAS scores. Thus, even though the POSA did meet the first set of validity criteria that we established (i.e., significant correlations with the three inventory measures), the self-ratings and examiner ratings did not. The significant negative correlations between self-ratings and two of the cognitive tests suggests that self-ratings may have been influenced by the children's awareness of the quality of their test performance.

To assess the contributions of individual POSA indicators to the correlations between the scale and the three inventory measures, the correlations of each of the 30 items with the three inventory scores were calculated. Most of these individual correlations were nonsignificant, suggesting that the predictive power of the indicators lies mainly in their combination with one another. Those corre-

lations that did attain statistical significance were lip contortions with PARSEP ($.39, p < .01$) and TSAS ($.43, p < .01$), gratuitous hand movement in the ear area with PARGEN ($.32, p < .05$), gratuitous hand movement at the top of the head with PARSEP ($-.38, p < .01$), gratuitous hand movement toward object with TSAS ($.53, p < .001$), gratuitous hand movement at other body part ($-.31, p < .05$), gratuitous leg movement with PARSEP ($.34, p < .05$) and TSAS ($.35, p < .05$), gratuitous foot movement with PARSEP ($.35, p < .05$) and TSAS ($.46, p < .01$), trunk contortions with PARSEP ($.29, p < .05$) and TSAS ($.42, p < .01$), and masturbation with PARGEN ($.39, p < .01$) and TSAS ($.58, p < .001$).

Anxiety Scores in the First and Second Sessions

As a second way of assessing the validity of the POSA, the mean POSA score for all children in the first session was compared with the mean score for all children in the second session (designed to be less anxiety producing than the first). As predicted, the children obtained significantly higher POSA scores in the first than in the second session, $t(28) = 2.53, p < .01$ (one-tailed). Of the 29 children, 22 had higher scores in the first than in the second session, $\chi^2(1) = 6.76, p < .01$. Further comparisons between the first and second sessions were made for children

Table 3
Comparisons of POSA Scores Between Sessions

Group	Session 1		Session 2		<i>t</i>	<i>df</i>
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>		
All children	61.4	21.3	51.3	14.0	2.53*	28
High PARSEP scorers	70.0	19.6	49.7	15.5	4.35**	14
High PARGEN scorers	64.3	19.2	49.0	14.3	3.17*	15
High TSAS scorers	61.4	22.4	47.6	14.0	2.66*	17

Note. POSA = Preschool Observation Scale of Anxiety; PARSEP = questions about the child's separation anxiety; PARGEN = questions about the child's general anxiety; TSAS = Teachers' Separation Anxiety Scale.

* $p < .01$, one-tailed.

** $p < .001$, one-tailed.

who scored above the median on the PARSEP, PARGEN, and TSAS, since it was thought that these children might be especially sensitive to the situational manipulations of stressors. Again, the high scorers on the three questionnaire scales showed significantly more behavioral indicators of anxiety in the first than in the second session. The results for these analyses are shown in Table 3. Note that in each of the three groups, the magnitude of the Session 1–Session 2 difference is greater than for the entire sample. In fact, of the four groups, children rated by their parents as high in separation anxiety showed the highest mean POSA scores during Session 1 with mothers absent and the largest Session 1–Session 2 difference—more than doubling the difference shown by the full sample.

Session 1–Session 2 differences were also calculated for the children's self-ratings and the examiner ratings. The change in the children's self-ratings from Session 1 to Session 2 indicates a nonsignificant increase in anxiety, whereas the change in the examiners' ratings indicates a highly significant decrease. Anxiety ratings on the children's 6-point picture scale averaged 2.22 in Session 1 and 2.59 in Session 2 ($p = .28$). Ratings on the examiner's 6-point scale averaged 3.07 in Session 1 and 2.00 in Session 2, $t(29) = 3.71$, $p < .001$. Thus, both the POSA and examiner ratings of anxiety met the second validity criterion, that is, significantly higher scores in Session 1 than in Session 2.

Finally, Session 1–Session 2 differences for each of the 30 POSA indicators were

calculated in an effort to gauge the contribution of the individual indicators to the overall sessions difference in total POSA scores. As was true in the correlational analysis reported earlier, most individual item effects were nonsignificant, suggesting that the discriminative power of the indicators lies principally in their combination with one another. However, there were five indicators that had significantly different frequencies in Sessions 1 and 2 (all in the predicted direction): silence to one question ($p < .05$), touching mouth area ($p < .01$), gratuitous arm movement ($p < .001$), trunk contortions ($p < .001$), and rigid posture ($p < .05$).

Discussion

The results of the present study support the use of the POSA as a measure of anxiety in young children. Independent judges achieved strong agreement on both total POSA scores and total scores for most of the 30 individual indicators. The large number of indicators used seemed to interfere with interobserver concordance at the micro level of 1-min observation blocks (at least by the most rigorous method of analysis); and this suggests that the two observers may have differed frequently in the particular behavioral incidents that they observed. Yet, this is a relatively trivial limitation considering the high interobserver correlations obtained for total POSA and individual indicator scores. In sum, the difficulties introduced by requiring observers to watch for

30 indicators appear to be outweighed by the value of including a variety of potential anxiety manifestations in order to capture indications of anxiety in individuals with differing expressive styles.

Two types of evidence support the view that the POSA yields a valid index of anxiety. As predicted, the scale was significantly correlated with all three inventory measures of anxiety. Also as predicted, the POSA yielded significantly higher scores during a presumably high-anxiety test session than during a session designed to provoke less anxiety. The data generally supported our original belief that broad-based measures such as the POSA would outperform simpler approaches such as self-ratings by young children and global judgments by examiners. Children's self-ratings and examiner ratings did not correlate significantly with any of the three inventory measures, with POSA scores, or with each other. Self-ratings showed very slight differences (and in the wrong direction) between Sessions 1 and 2; however, Session 2 ratings by the examiner were significantly lower than Session 1 ratings. It is uncertain whether this latter finding derived from an expectation by the examiner that children's anxiety would be lower in the second session with mothers present. However, whatever the basis for the finding, it constitutes the only bit of evidence supporting the use of either self- or examiner ratings. This pattern of findings seems to indicate the superiority of structured observations of carefully delineated behaviors over global, unstructured, and thus subjective ratings, though this conclusion must be qualified by the fact that the structured observations were made by trained observers, whereas the global ratings were not.

As indicated in the Introduction, the relation between anxiety and problem-solving performance appears to be quite complex. In the present study none of the inventory measures was significantly related to test performance, and the POSA was significantly related only to Digits performance ($r = .38$). So, anxiety, as measured by the POSA and inventory scores, did not appear to have a debilitating effect on test performance for

children in the present study, and may have had an enhancing effect on one test, perhaps due to factors related to the high socioeconomic status of the present subjects.

Further research with the POSA should include investigations of the scale's capacity to reflect the effects of stressors other than those devised in the present study. Children varying more widely in age and other demographic characteristics than those of the present sample should be included. And, more importantly, there is a need to assess the scale's usefulness with clinical populations of children who (unlike those of the present sample) suffer from pronounced behavior problems. In addition, research using longer observation periods than the 10-minute-plus sessions of the present study could be useful; some behaviors that did not occur in the relatively brief sessions of the present investigation might prove to be useful indices of anxiety if children were given a lengthier opportunity to display them. Even the behaviors that occur infrequently might well prove to be potent anxiety indicators when they do appear. Finally, the degree of anxiety is apt to be reflected not only by the *frequency* of anxiety behaviors but also by their *intensity*. Although intensity may be difficult to quantify, its potential for increasing the precision of anxiety measurement would seem to justify efforts in this direction.

For the present, however, the POSA represents a potentially useful approach to the assessment of anxiety in children. Given the sensitivity of the POSA to situational variations in stressors, the scale itself should be particularly useful to researchers concerned with the interplay between specific situational conditions and affective states (e.g., Spielberger et al., 1972). In addition, the POSA could contribute usefully to our understanding of sex differences in anxiety manifestations at various ages (see Maccoby & Jacklin, 1974, pp. 182-190), and to our capacity to evaluate therapeutic techniques for children (see Achenbach, 1974, pp. 606-650). Research on these topics, focusing on anxiety states in children, clearly must circumvent the problems of projective techniques, self-reports, global and subjective

observer reports, and physiological measures, all outlined in the Introduction. The evidence presented in the present study suggests that instruments such as the POSA may provide logical, valid, and reliable alternatives to these more traditional approaches.

Diagnostic Validity of a Standardized Neuropsychological Battery Derived from Luria's Neuropsychological Tests

Charles J. Golden

University of Nebraska Medical Center

Thomas A. Hammeke and Arnold D. Purisch

University of South Dakota

The work of A. R. Luria has been recognized as a major contribution to neuropsychology. Among his accomplishments, Luria has devised an extensive set of procedures used for neuropsychological evaluation. Luria's tests permit the full identification of the specific deficits underlying a disorder and can be completed in about 2 hours. The most significant flaw in the battery is a lack of standard administration and scoring that has precluded an assessment of its validity. The present study was an attempt to overcome these deficiencies by developing an objective form, combining Luria's procedures with the advantages of a standard test battery. The resultant test was evaluated using 50 medical control and 50 neurological patients. Of the 285 measures in the battery, 253 significantly discriminated at the .05 level, and only 16 failed to discriminate at the .2 level. A discriminant analysis, using the 30 most effective items, yielded a hit rate of 100%. The battery's potential and the future research necessary are discussed.

The work of A. R. Luria, the Russian neuropsychologist, has been internationally recognized as a major contribution to experimental and clinical neuropsychology. Luria has made extensive theoretical contributions (e.g., Luria, 1963, 1966, 1970, 1973) and has devised numerous clinical diagnostic and rehabilitation procedures (e.g., Luria, 1963, 1966). Many of Luria's diagnostic procedures have recently been published by Christensen (1975a, 1975b) along with the equipment necessary to perform these tests (Christensen, 1975c).

Luria's tests are based on his theoretical contributions to neuropsychology. Luria envisions the brain divided into three principal units responsible for arousal, sensory input and integration, and behavioral planning and execution. In turn, the areas within each of

these units have specific functions. For example, one area within the second functional unit is responsible for auditory input, and another area is responsible for the integration of visual and auditory stimuli.

Within Luria's system, overt behavior is the result of the cooperation among different areas of the brain. The pattern of interacting areas responsible for a given behavior is called a functional system. Each area of the brain participates in numerous functional systems.

The effect of any brain injury is to interrupt the execution of any functional system that includes the injured area(s). Thus, any brain injury will effect the performance of numerous behaviors. The generality of the behavioral loss depends on the importance of the functional systems interrupted, as well as the availability of alternate functional systems to replace the injured system.

The role of the neurodiagnostician is to isolate the specific point at which a client's functional systems have been interrupted. This requires a detailed evaluation of a sub-

Requests for reprints or for additional information on the battery should be sent to Charles J. Golden, Nebraska Psychiatric Institute, University of Nebraska Medical Center, Omaha, Nebraska 68105.

ject's intact and interrupted functional systems. From the pattern of performance deficit discovered, the specific locus of the brain injury can be determined, as well as such factors as type and severity of the disorder.

Thus, Luria's diagnostic tests consist of numerous specific procedures. These are designed to isolate dysfunction, compared to the more global assessments characteristic of many neuropsychological tests. In addition, Luria's procedures tend to be qualitative in nature, rather than quantitative.

Luria's procedures have several practical advantages. First, they provide a more extensive breakdown of behavior than can be determined from more global tests. Thus, the clinician can derive a more specific analysis of the deficits present in a patient. This information can be used for both neurodiagnosis and for specific rehabilitation planning based on an individual's pattern of test results (Golden, 1976, 1978; Luria, 1963).

A second advantage of these test procedures is the ability to do a full examination in less than 2.5 hours (Luria, 1966). In contrast, a test battery like the Halstead-Reitan, which can reveal similar deficit patterns, may take from 6 to 8 hours. A third advantage of the Luria tests is their portability. Luria's procedures were specifically set up to be done at bedside with a minimum of inexpensive equipment. Again, this is in contrast to many current test procedures that require a laboratory setting or great amounts of equipment, sometimes costing several hundred dollars.

Finally, the Luria battery includes an evaluation of all of the areas necessary for a complete neuropsychological exam (Benton, 1975). This includes evaluation of motor functions, sensory skills (auditory, tactile, and visual), verbal skills (expressive speech, receptive speech, reading, and writing), spatial skills, mathematical abilities, memory, and intellectual skills.

Despite these advantages, the Luria tests have been widely criticized. One significant problem has been the lack of any direct evaluation of the tests beyond Luria's own observations and conclusions. In this regard,

Reitan (1976) has written that Luria's "reports essentially represent evaluation of 'critical cases' based upon his own observations, conclusions, and statements of significance" (p. 199). This lack of systematic validation has greatly limited the generalizability of Luria's results.

A major problem in a validation study is the lack of any *standardized* method of giving or scoring Luria's test procedures. In many cases, the description of administrative procedures is vague. Moreover, Luria acknowledges changing procedures for individual patients. Even when administrative procedures are clear, scoring procedures are not. Scoring is determined by the personal assessment of the clinician based on experience and knowledge rather than on any normative data.

Despite these major problems, the Luria battery clearly possesses a high degree of face validity as well as a strong theoretical foundation. With proper standardization, scoring, and validation, the Luria tests could become a major tool of both clinical and experimental neuropsychology.

Development and Rationale

The intention of the present study was to use the material presented by Luria (1966, 1973) and Christensen (1975a, 1975b, 1975c) to form a standardized, objectively scored version of Luria's neuropsychological procedures. The new battery was designed to retain, as closely as possible, the qualitative nature of Luria's tests and the sampling of all the major areas of neuropsychological performance.

At the same time, the standardization of the items and the objective scoring would allow for careful validation and replication of the test results, as well as for the systematic collection of data on a wide variety of neurological disorders. This would allow the development of scales representing specific loci of injury or underlying causes in order to establish a firmer interpretation of the battery.

Consequently, the battery, as envisioned, would have the advantages of a detailed,

qualitative analysis of a client's behavior, as well as the advantages of a standardized quantitative battery and the systematic diagnostic research that can be completed with such a battery. In addition, the battery would have the advantage of a relatively short testing time.

The first step in designing the battery was to develop standardized items, keeping as close as possible to the original procedures while creating items that could be objectively scored. After the development of the initial items, they were administered to a clinical population to evaluate their practicality.

As the project progressed, numerous items were rewritten or deleted as they were found to be ineffective or duplicative. Others were eventually discarded when a reliable scoring system could not be developed for them. Some items were eventually found to be too difficult to administer to an impaired population. After 6 months of effort, a final version of the test to be used in this study was developed.

Present Study

The purpose of the present study was an initial validation of the standardized battery. Fifty normal hospitalized subjects were compared with 50 brain-injured subjects. *t* tests were calculated on each score within the battery. In addition, a discriminant analysis was used to measure the overall effectiveness of the battery.

Method

Subjects

The subjects were 100 hospitalized patients tested in hospitals in Sioux City, Iowa; Yankton, South Dakota; and Sioux Falls, South Dakota. Fifty subjects had confirmed neurological diagnosis made on the basis of medical exams alone by a qualified physician, usually a neurologist or neurosurgeon. The control subjects had a variety of medical problems including back injuries, infectious diseases, and chronic cases of pain.

The average age of the control subjects was 42.0 years ($SD = 14.8$ years), and the average age of the experimental subjects was 44.3 years ($SD = 18.8$ years). The difference in age was not significant,

$t(98) = .7$, $p > .40$. Overall, there were 49 females and 51 males. No significant differences in sex distribution were present in the two groups.

The control group had 12.21 years ($SD = 2.86$ years) of education, and the neurological group had 10.30 years ($SD = 2.84$ years). The difference between the groups was significant, $t(98) = 3.51$, $p < .01$.

Test Battery

Overall, the Luria-South Dakota Neuropsychological Test Battery consists of 285 measures and can be administered in less than 2½ hours to a significantly impaired individual. The battery requires several pieces of inexpensive equipment. First, a series of cards with pictures and word items published by Christensen (1975c) are needed. Several additional pictures (available from the first author) are necessary to replace some of the Christensen items that were found to be ineffective with an American population.

In addition, the battery requires the following objects: (a) a 13-cm black comb; (b) a 2½ × ½ inch (5.5 × .6 cm) rubberband; (c) a paper clip, jumbo size; (d) a Bow Compass 5178 (available from the Empire Pencil Company, Shelby, Tennessee 37160); (e) a Pedigree Quality Eraser 2910 (also available from the Empire Pencil Company); (f) a key (WR2 Curtis 177); (g) a straight pin; (h) a quarter; (i) a metric ruler; and (j) an audiotape for some of the rhythm and verbal items.

The items in the battery are generally adapted from Christensen (1975a, 1975b, 1975c)² with slight modifications as necessary in order to establish a standard administrative or scoring procedure. The items fall roughly into 10 categories:

Motor functions. This section includes a series of tasks requiring the reproduction of simple motor movements with the hands, mouth, and tongue, both when a model is provided and under verbal instructions alone. The section also evaluates simple coordination, optical-spatial organization, complex sequencing of behavior, and the ability to draw. Sample items on this scale include:

1. Using your right hand, touch your fingers in turn with your thumb as quickly as you can

¹ Information on obtaining the materials used in the battery, copies of the battery, and the current test manual can be obtained from the first author.

² The items in the battery have been modified from Luria's Neuropsychological Battery with permission. (Copyright 1975 by Anne-Lise Christensen and Munksgaard, Copenhagen, Denmark, and Spectrum Publications, Inc., 1975-20 Wexford Terrace, Jamaica, New York 11432.)

while you count them. [with palm facing up, demonstrate and then have the subject practice before timing. Allow 10 sec. Score the number of complete times the subject does the sequence accurately.]

5. Close your eyes and place your right hand in the same position as I place it first. [Press thumb against fifth finger for 2 sec., then return to normal position. Score correct or incorrect.]

11. Do as I do. [Place right hand under chin with fingers bent.]

22. With your hands in front of you, tap your right hand twice and your left hand once, changing smoothly from one hand to the other like this. [Demonstrate and allow the subject to practice.] Do this as quickly as you can until I tell you to stop. [Allow 10 sec. The score is the number of fully correct sequences.]

25. Show me how to work with scissors.

36. Without lifting your pencil from the paper, I want you to draw the best square you can. [Score for time and quality. All quality items have objective grading requirements in the test manual.]

44. [Show picture of a square]. Draw this. [Score as above].

50. If I knock once, raise your right hand, if I knock twice, raise your left hand. [Give four trials, alternating one and two knocks. Score number of errors.]

Rhythm (acoustico-motor functions). This section includes items requiring the individual to differentiate between sounds with different pitch and rhythmic relationships. The subject must indicate whether sounds are the same or different as well as whether they reproduce rhythmic and pitch patterns. Sample items included:

52. Now you are going to hear two tones on a tape. Tell me whether the tones are the same or different. [Play six pairs of tones. The score is the number of errors.]

53. Again, you will hear two tones. Tell me which is higher, the first or second tone. [Play tape with five pairs. Score errors.]

58. Tell me how many beeps you hear. [Play four groups of beeps from tape. Score number of errors.]

62. You will now hear a rhythm on the tape. When I tell you that the rhythm is over, I want you to tap with your hand the rhythm you heard on the tape. [Play three rhythms. Score as right or wrong.]

Cutaneous and kinesthetic functions (tactile). This section evaluates complex cutaneous function, muscle and joint sensations, and stereognosis. Kinesthetic assessment requires a blindfolded subject to identify the direction of limb movements and reproduce limb positions. Cutaneous assessment includes evaluation of threshold, localization, stimulus identification, and two-point finger discrimination. The assessment for stereognosis requires a blindfolded subject to identify common objects placed in the palm of the hand under both active and passive palpating conditions. Sample items include:

64. Tell me where I am touching you. [Have blindfolded subject in sitting position with hands in front and palms facing up. Touch the subject with the eraser end of pencil, alternating among right and left fingers (numbered 1-5), palms (P), forearms (F), and shoulders (S). If uncertain of where the subjects report touch from verbal report, have the subjects indicate the place touched with their opposite hand. Touches should be in the following order:

Right hand: 1 F 3 5 P 2 S 4
Left hand: P 2 3 S 5 4 F 1

Score for number of errors on each hand.

80. Now I will put your left arm in a certain position; try to put the other arm in the same position. [Extend left arm of blindfolded subject in front at 90°.]

82. Feel this object and tell me exactly what it is. [Instruct the subject to hold their right palm up and place objects on the fingers. Alternate between hands in this manner. Allow 10 sec per item. Score for correctness of answer, and time each response. Objects include quarter, key, eraser, and jumbo paper clip.]

Visual functions. This section includes a series of tasks assessing the integrity of visual-spatial perception, including the identification of objects and pictures, identifying the missing elements in complex geometric configurations (similar to the tasks in Raven's Progressive Matrices) and constructing geometric patterns from blocks. Subjects must identify time on clocks with no numbers and show spatial and directional orientation. Finally, the ability of a subject to perform spatial rotations and transformations is assessed.

Sample items include:

86. What do you call this object? [Examiner presents the subject with objects one at a time. Allow 10 sec per item. Items are pencil, eraser, rubber band, and quarter.]

87. What is this picture supposed to be? [Present pictures one at a time and allow 10 sec for each.

Pictures include a purse, a nut cracker, a glass vial, a camera, and an egg carton. Score the number wrong.]

88. [Show clock faces.] Tell me what time these clock faces show.

97. This drawing shows a stack of blocks in three dimensions. Tell me how many blocks are in the stack. [Be sure to include those you see as well as those you don't see.]

Impressive speech. This section assesses a subject's ability to discriminate basic English phonemes and to reproduce the discriminations orally or by writing; to name familiar and unfamiliar objects among a series of pictures; and to respond to statements and questions that require the understanding of genitive, prepositional, comparative, and complex grammatical constructions.

Sample items included:

100. You will hear some sounds on the tape. What I want you to do is first repeat exactly the sound you hear and then write down the letter of the alphabet that goes along with the sound. For example, if you hear the sound "ta," you would say "ta" and then write down the letter "t". [Score oral and writing errors separately.]

110. I will place some pictures before you. I want you to point at the shoe, the candle, the stove.

114. Put your hand on your head.

125. Which boy is shorter if John is taller than Peter?

130. Is the following sentence said by a disciplined or an undisciplined person? "I am unaccustomed to disobeying rules."

Expressive speech. This section includes tasks requiring the articulation of simple speech sounds, familiar and unfamiliar words of varying lengths, and phrases or sentences of varied length and complexity. The test also requires the subject to name and classify objects and to produce narrative descriptions.

Sample items include:

133. Repeat after me: (a) a (as in late); (b) i (as in light); (c) m (as in milk) (d) b (as in baby); and (e) sh (as in shine).

137. Repeat after me: (a) hairbrush, screwdriver, laborious.

138. Repeat after me: house-ball-chair. [Say all three as one item].

157. What objects do these pictures represent? [Show five pictures.]

163. Say the days of the week backwards starting with Sunday.

164. Tell me what's happening in this picture. [Present picture. Score time to respond and number of words in first five seconds of response.]

Reading and writing. This section requires the subject to break words into their component sounds or letters; to integrate sounds or letters into words; to copy letters and words; to write words of varying complexity from dictation; and to read sounds, words, phrases and paragraphs.

Sample items:

178. Copy these in your own handwriting. [Present card.]

183. Write these words [dictate]: wren, knife.

188. What sound is made by the letters (a) g-r-o and (b) p-l-y.

192. Read these sounds [Present card with the sounds po, cor, cra, spro, and prot.]

197. Read these sentences. [Present cards.]

Arithmetical skills. This section requires a subject to identify Arabic and Roman numerals, to identify the significance of digit placement, to compare numbers of varying size, and to do simple arithmetic operations (multiplication, addition, subtraction) and simple algebraic manipulations. The ability to form arithmetic series is also evaluated. Items are presented both orally and visually.

Sample items:

203. Write these numbers: 71, 17, 69, 96.

206. Read these numbers [on card]: 7-9-3, 3-5-7.

210. Tell me which is larger: 17 or 68? 23 or 56? 189 or 201?

216. Add these numbers in your head: 5, 9, 7.

219. What is the missing number [Present card with the following:]

$$12 - \underline{\quad} = 8.$$

$$12 + \underline{\quad} = 19.$$

Mnemonic processes. This section involves a series of tasks assessing an individual's retention and retrieval skills for visual, acoustic, and kinesthetic inputs. Subjects must work with both verbal and nonverbal material. The effects of retroactive and proactive interference are also examined.

Sample items:

227. I am going to show you a card, and I want you to look at it carefully. When I remove the card, I want you to draw as much from it as you can remember. [Present card for 7 sec.]

231. I want you to remember some words that I am going to say: house-tree-cat. Now, look at this picture; what do you see? [Allow the subject to describe the picture for 15 sec.] What were the words?

Intellectual processes. This section requires the subject to interpret the themes of pictures, to demonstrate vocabulary skills, to form concepts, to classify objects, to understand analogies, to complete complex arithmetical problems, and to show logical reasoning skills.

Sample items:

245. What is meant by the expression "iron hand"? "green thumb"? [Score for quality.]

249. In what way are table and sofa alike? In what way are an ax and a saw alike?

256. What has the same relation to good as high has to low?

258. Peter had two apples and John had six apples. How many did they have together?

Other items in the test, in addition to the examples shown, test the same processes, varying the difficulty, modality involved, instructions, or hand that is used.³

Procedure

In the case of each potential subject, written permission was obtained to review medical records in order to assess whether the subject met the necessary requirements of a confirmed diagnosis for the study. Individuals whose diagnosis was questionable as to the presence or absence of brain injury were not included in the study, unless a definitive diagnosis was later established.

Once a patient had assented to participate, administration was arranged at a time that did not interfere with the hospital schedule. The majority of test administrations occurred at bedside, although free rooms for testing were occasionally available. Because of the relative short time needed to administer the battery, the testing was done in a single session. In some cases, however, the session was divided by visitors or hospital tests.

Scoring

Items were scored by a variety of methods according to the nature of the item and the quali-

tative dimension or dimensions that were to be assessed by the item. As can be seen in the sample items already presented, many items could be scored as right or wrong, or the overall number of errors could be counted on an objective basis. Time to complete an item or latency of response was also frequently used. Other scoring criteria included frequency of response in a specified time, trials to correct performance, and number of items completed. In some cases, quality of response was judged. The test manual gives extensive instructions on the evaluation of such responses.

For all items, the raw scores were recorded and then converted into a 0, 1, 2 system. A score of 0 was intended to represent the performance characteristic of a normal individual. A score of 1 represented performance intermediate to that of normals and brain-damaged patients. A score of 2 represented performance characteristic of brain damage. The scoring for each item was established by finding cutoff points that maximized the discriminative effectiveness of the item in a group of 75 subjects collected early in the development of the battery (37 normals, 38 brain damaged). This was done by maximizing the chi-square that compared the number of subjects in each category who were diagnosed correctly or incorrectly.

Alternate scoring systems were also tried that contained wider ranges, including a 0, 1, 2, 3 system and a 0, 1, 2, 3, 4 system. However, these failed to add any additional discriminative validity to the tests. Hence, it appears that the simpler system should be used. For researchers wishing to compare scores on tests more finely, the raw score data allow this to be accomplished.

To evaluate the reliability of the scoring system, the test was administered by 1 examiner in the presence of a second examiner. Each examiner scored the test independently. This procedure was repeated for five patients. In each repetition, a different pair of examiners was used; thus the procedure involved 10 examiners. Overall, there were 1,425 pairs of scores available. The rate of agreement was over 95%.

Results

t tests were run between the control and neurological group on all 285 scores generated by the test. Of the 285 comparisons made, 253 were significant at the .05 level ($df = 98$). In all cases, the neurological group performed less effectively (a higher score) than the control group. Of the 32 items not significant at the .05 level, 16 exceeded the .20 level of probability. On these

³ Copies of the text, a test manual describing scoring criteria, and procedures for each item are available from the first author.

32 items, the neurological group performed poorly on 30 items and showed identical performance on two items.

Because of the educational differences between the groups, one-way analyses of variance were calculated using education as a covariate. In no case did any significant item become nonsignificant because of the control of the educational difference, although education contributed a small amount of variance to each item. In no case did a nonsignificant item become significant because of the use of the covariate.

To further evaluate the potential effectiveness of the battery, a discriminant analysis was run using all 285 measures. It was found that a weighted, linear combination of 30 variables was sufficient to separate the groups with 100% accuracy.

Discussion

The results of the current study clearly supports the validity of the standardized battery. Nearly 90% of the items suggested by Luria, and modified so as to be objective, significantly discriminated between the brain-injured and normal subjects. In addition to the excellent results with the individual items, the discriminative analysis achieved a 100% hit rate using only 30 of the 285 scores. This result is comparable to the results achieved by a neuropsychological test battery of any kind. It is recognized that the hit rate might not be as high in a cross-validation. Despite this, the results clearly illustrate the strong potential of the assessment approach reflected in the battery.

An evaluation of those items that failed to discriminate between groups revealed no consistent pattern. Some of the items were too easy and were missed by no one, such as "Show me your teeth." Others were clearly quite difficult: "Which is correct, 'The earth is illuminated by the sun' or 'The sun illuminates the earth'?" (Correct answer: Both are correct). In other cases, no fully comprehensive scoring method could be devised. In this category, one deceptively simple item "Show me how to frown" resisted repeated attempts to devise an effective scoring procedure.

Despite the impressive results of the current study, there is a need for more extensive research before the battery can be used in clinical situations on a regular basis. One important research goal will be the establishment of a basic summary scoring system so that performance in general areas (spatial skills, speech, cognition, among others) can be easily determined and compared.

A second research area is the demonstration of the effectiveness of the battery in a population including psychiatric patients, a setting in which extensive neuropsychological evaluation takes place. It is necessary to examine the effectiveness of the battery with psychiatric patients who have a chronic history and a long duration of hospitalization, subjects for whom neuropsychological tests are often highly ineffective (Golden, 1977, 1978; Lezak, 1976).

A third research area is assessing the ability of the battery to localize injuries and aid in the identification of underlying neurological processes. Luria's theoretical system suggests that the battery should be highly effective in this regard, perhaps more effective than any other comparable neuropsychological battery.

In this regard, it may also be possible to develop scales designed to specifically measure such factors as laterality, localization, or process. This scale development would be analogous to the process used with the Minnesota Multiphasic Personality Inventory and other similar tests.

The final area of necessary research is to examine the effects of variables such as age, education, medication, intelligence, chronicity, and severity of a disorder. As the effects of these variables are determined, appropriate clinical procedures can be devised to correct for these factors or to include them in a clinical analysis.

In addition to its usefulness in neurodiagnosis, the battery is a potential useful instrument in rehabilitation planning. As was seen in the Method section, the battery evaluates a wide range of abilities, allowing the clinician to identify the specific areas in which an individual has problems as well as the underlying deficits in an individual's functional systems caused by a brain injury.

There is also the ability to evaluate those abilities that remain intact. This information can be used to plan rehabilitation tasks designed to retrain a lost ability or to use intact abilities to reformulate a functional system (Golden, 1976, 1978; Luria, 1963). This potential of the battery requires careful and systematic evaluation by rehabilitation psychology.

At present, we are carrying out further studies aimed at meeting some of the important research requirements outlined above. The present study clearly indicates that the standardized Luria battery has tremendous potential and may be the extensive, highly effective, economical, and standardized battery that neuropsychology will need as the field grows into more diverse settings. Future research should determine the extent to which the battery fulfills this potential.

Discrimination of Schizophrenic and Brain-Injured Patients by a Standardized Version of Luria's Neuropsychological Tests

Arnold D. Purisch
University of South Dakota

Charles J. Golden
University of Nebraska Medical Center

Thomas A. Hammeke
University of South Dakota

This study examines the ability of a standardized battery of tests suggested by the extensive work of A. R. Luria to discriminate between brain-injured and schizophrenic patients. An earlier study reported 93% effectiveness for the standardized battery in discriminating brain-injured patients and normal controls. In the present study, the battery was administered to 100 schizophrenic and brain-injured patients. Chronicity was 121 months ($SD = 125$) for the schizophrenic group and 56 months ($SD = 116$) for the neurological patients. Of the 282 items in the battery, schizophrenics showed significantly better performance on 72 items ($p < .05$). A discriminant analysis using 60 items demonstrated 100% diagnostic accuracy. Schizophrenics performed better on 10 of 14 summary measures ($p < .01$). A discriminant analysis using the 14 summary measures achieved 88% diagnostic accuracy. The accuracy shown by the battery is as high as the results obtained using other tests in a comparable chronic schizophrenic sample. The usefulness of the battery in schizophrenic and brain-injured patients is discussed.

The differential diagnosis between psychological problems due to schizophrenia and those due to brain injury is a significant issue in the field of clinical neuropsychology. Several diagnostic instruments have been developed for this purpose, ranging from short, individual test procedures such as the Bender-Gestalt to long test batteries such as the Halstead-Reitan.

Despite many attempts to find the ideal test or tests, no instrument yet developed consistently separates schizophrenic from brain-injured groups. Although many studies have reported statistically significant group differences (Yates, 1954, 1966), these results do not reflect the real clinical utility of a test. A test can discriminate between groups on the basis of mean differences in performance, but there may still be too much over-

lap between members within each group to allow accurate individual diagnosis. Therefore, the major measure of clinical effectiveness is the hit rate—the percentage of patients accurately diagnosed by a test (Yates, 1954).

Unfortunately, many studies do not report hit rates (Spren & Benton, 1965). Studies that have reported hit rates when evaluating the diagnostic effectiveness of an assessment technique in discriminating between schizophrenic and brain-injured patients have indicated a wide scope of results ranging from chance levels of 50% to over 90% accuracy. Generally, no test or test battery has shown consistently good results in studies using psychiatric patients (see Golden, 1978).

Three primary factors have been identified by various reviewers to explain the inconsistent results in the literature: differences in chronicity of schizophrenia, the comprehensiveness of assessment procedures, and the methods of data analysis (Davison, 1974). In general, chronicity is positively related to

Requests for reprints and copies of the test and test manual should be sent to Charles J. Golden, Nebraska Psychiatric Institute, University of Nebraska Medical Center, Omaha, Nebraska 68105.

decrements in adaptive functioning as measured by a wide variety of psychometric tests. Long-term chronic schizophrenics are likely to reveal deficits similar to those seen in neurological patients. The majority of studies reporting nonsignificant results or low hit rates have used long-term chronic schizophrenics. For example, Watson and his collaborators (Watson, 1968, 1972; Watson, Thomas, Andersen, & Felling, 1968; Watson, Thomas, Felling, & Andersen, 1968; Watson, Thomas, Felling, & Andersen, 1969; Watson & Ueker, 1966) tested schizophrenics who had an average length of hospitalization of over 10 years. Those studies reporting positive results have used schizophrenics with generally short hospitalizations of under 1 year and less severe disorders (e.g., Golden, 1977).

A second factor is the ability of the tests to assess all neuropsychological skills. Organicity cannot be considered as a unitary entity resulting in identical disturbances across patients (Boll, 1974). In a mixed brain-injured group, the differences in the nature and loci of lesions for each individual result in unique patterns of disturbed functioning. Procedures not providing comprehensive assessment may fail to reveal lesions that manifest disturbances in abilities other than those included in the assessment. Accordingly, the Halstead-Reitan, presently the most comprehensive standardized test battery, has been able to demonstrate the highest hit rates with neurologically impaired populations (Golden, 1977).

Another problem exists with some of the commonly used tests of brain damage. These tests are comprised of items that require the concerted working of several neuropsychological abilities (Lezak, 1976). These types of tasks are often so complex that even non-organic subjects, particularly schizophrenics, may perform poorly. As a result, many patients without neurological problems may be falsely diagnosed as organically impaired. For example, poor performance on the Bender-Gestalt may not be a positive indicator of brain damage; it may simply reveal psychological dysfunction without regard to etiology (Golden, 1977).

The method of analyzing test results is a

third factor to consider in evaluating the efficacy of various diagnostic instruments. Most studies of tests that do not demonstrate significant group differences have based their comparisons on global measures representing overall test performance. Performance on individual test items is obscured in these global measures, and much potentially useful diagnostic information is lost. As such, global quantitative comparisons may not be a fair method of assessing a test's true diagnostic effectiveness (Lezak, 1976). For example, Goldstein and Neuringer (1966) argued that a qualitative analysis of the Trail Making Test, part of the Halstead-Reitan, increased hit rates to nearly 80%, whereas global scores were only able to achieve separation at chance levels. Hewson (1949a, 1949b) demonstrated up to 90% diagnostic accuracy using analyses of Wechsler Adult Intelligence Scale (WAIS) subtest relationships, whereas studies comparing group mean performances did not show consistent significant differences (Matarazzo, 1972).

The statistical methods that are used may also affect the results of a study. Many studies have used univariate tests to detect group differences for each measure under consideration. This practice may result in lower hit rates than when maximum information is obtained by combining tests. A study by Golden (1978) demonstrated more reliable discrimination between schizophrenics and brain-injured subjects when the results of all measures in a test battery were statistically combined by a discriminant analysis than when each measure was considered separately by *t* tests.

A. R. Luria, the Russian neuropsychologist, has developed a set of procedures intended to assess systematically each area of neuropsychological functioning. Based on Luria's extensive theoretical contributions to neuropsychology (e.g., Luria, 1966, 1973), the items yield a qualitative assessment of the major neuropsychological skills.

Luria's procedures have several advantages. First, they allow for a comprehensive assessment of neuropsychological abilities. Second, complex behaviors are systematically analyzed by items assessing specific neuro-

psychological skills. This feature provides information about the qualitative nature and degree of a disturbance that can be useful for diagnostic and rehabilitative purposes (Luria, 1963). Finally, a relatively short administration time makes it more likely that a patient's attention and interest can be sustained (Golden, 1978; Smith, 1975). These characteristics suggest that it should be a highly useful diagnostic instrument, even in chronic schizophrenic populations.

Despite these advantages, the tests have been criticized. Stressing the importance of flexibility when testing neurological patients, Luria does not provide a standard manner in which to administer his tests. Instead, he recommends modifying procedures as necessary to account for patient needs and specific referral questions. In addition, Luria does not provide for rating responses. Judgment and clinical intuition are the methods of test interpretation rather than comparisons to normative standards. Reitan (1976) has criticized the lack of standardization and the lack of scoring criteria, contending that Luria's opinion is the only measure of validity that has been used with the battery.

As a result of these criticisms, we (Golden, Hammeke, & Purisch, 1978) developed an alternate version of Luria's battery. We attempted to eliminate the weaknesses dis-

cussed above while maintaining the positive features. Standard administration procedures were defined, and a scoring system was developed. The scoring included separate scores for the important dimensions of each response. Another consideration was to keep administration time as short as possible without sacrificing comprehensiveness.

Hammeke, Golden, and Purisch (in press) has shown the standardized battery to be highly effective in discriminating brain-injured and hospitalized control patients. We found that the individual items in the test discriminated experimental and control patients 100% of the time. We also found that a combination of 14 summary scores could achieve a 93% hit rate. These rates are as good as or better than the results seen in any other single test or test battery (e.g., see Golden, 1977; Lezak, 1976).

Since the discrimination of brain-damaged and schizophrenic patients appears to be the most difficult task for a neuropsychological test battery or procedure, the present study is an attempt to evaluate the effectiveness of the standardized version of Luria's tests when comparing these two populations. If the test is able to make this discrimination, then the clinical value of the Luria in diagnostic work would be strongly increased.

Method

Subjects

The subjects were 100 hospitalized patients. All were approached at the recommendation of their physician, and all volunteered to participate in the study. Fifty subjects had confirmed neurological diagnoses made on the basis of medical examination by a qualified physician, usually a neurologist or neurosurgeon. The 50 other subjects were patients diagnosed by psychiatrists as having a schizophrenic disorder. No schizophrenics were included for whom there was a possibility of organicity as indicated by a history of seizures, alcoholism, or head trauma. Table 1 presents the diagnostic subtypes of both the schizophrenic and brain-injured subjects.

Overall, there were 56 male and 44 female subjects. No significant difference in the sexual distribution of the two groups was present. Other background data were obtained from the subjects' hospital files after securing their signed informed consent. Table 2 presents the means and standard deviations of each group for age, education, length of hospitalization, duration of illness (chronicity), age of onset of illness, and number of previous hospitalizations.

Table 1
Frequency and Percentage of Diagnostic Subtypes for Brain-Injured and Schizophrenic Subjects

Diagnostic subtype	f	%
Neurological diagnosis		
Cerebral trauma	10	20
Neoplasms	6	12
Infectious diseases	3	6
Cerebral vascular disorder	14	28
Degenerative diseases	6	12
Epilepsy	4	8
Metabolic and toxic disorders	3	6
Congenital disorders	4	8
Schizophrenic diagnosis		
Catatonic	2	4
Hebephrenic	3	6
Paranoid	19	38
Simple	1	2
Undifferentiated	20	40
Schizoaffective	5	10

Table 2
Means, Standard Deviations, and *t* Tests for Demographic Indices

Index	Brain injured ^a		Schizophrenic ^a		<i>t</i> ^b
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>	
Age (years)	44.36	18.83	41.32	14.52	.90
Education (years)	10.30	2.84	11.38	2.59	1.97
Length of hospitalization (days)	19.62	43.38	410.42	1,569.32	1.76
Chronicity (months)	56.24	116.40	121.02	125.03	2.67**
Age of onset (years)	39.42	22.34	32.08	12.26	2.04*
Previous hospitalizations	1.50	2.05	4.29	3.48	4.79***

^a*n* = 50.

^b*df* = 98.

**p* < .05.

***p* < .01.

****p* < .0001.

This table indicates that schizophrenics had significantly higher means for chronicity and number of previous hospitalizations. Schizophrenics also had a significantly earlier mean age of onset compared to the brain-damaged subjects. Length of present hospitalization was considerably longer for the schizophrenics, but this difference was not significant. No significant group differences were found for age or years of education.

Test Battery

All of the items in the test battery were adapted from Christensen (1975a, 1975b, 1975c) with modification in order to establish standard administrative scoring procedures. The battery consists of 282 measures and can be administered in less than 2½ hours. The items fell into 10 categories.¹

Motor functions. This series of tasks requires the reproduction of simple motor movements with the hands, mouth, and tongue both when a model is provided and from verbal instructions alone. The section also evaluates simple coordinated abilities, motor-spatial organization, complex sequencing of behavior, and the ability to draw.

Acoustico-motor (rhythm) functions. These items require the individual to differentiate between sounds with different pitch and different rhythmic relationships. The subject must indicate whether sounds are the same or different and reproduce given pitch or rhythmic relationships played from a tape.

Cutaneous and kinesthetic (tactile) functions. This section evaluates complex cutaneous functions, muscle and joint sensations, and stereognosis. Kinesthetic assessment requires a blindfolded subject to identify the direction of limb movements and reproduce limb position. Cutaneous assessment includes evaluation of threshold localization, stimulus identification, and two-point finger and palm discrimination. The assessment for stereognosis requires a blindfolded subject to identify common objects placed in the palm of the hand.

Visual functions. These tasks assess the integrity of visual-spatial perception, including the identification of objects and pictures, identifying the missing elements in complex geometric configurations (similar to the tasks in Raven's Progressive Matrices), transposing pictures of blocks with no numbers, and showing spatial and directional orientation. Finally, the ability of a subject to perform spatial rotations and transformations is assessed.

Expressive speech. This section includes tasks requiring the articulation of simple speech sounds, familiar and unfamiliar words of varying lengths, and phrases or sentences of varied length and complexity. The test also requires the subject to name and classify objects and to produce narrative descriptions.

Impressive speech. The tasks require the articulation of simple speech sounds, familiar and unfamiliar words of varying lengths, and phrases or sentences of varied length and complexity. The subject must name and classify objects and produce narrative descriptions.

Reading and writing. The subject must break words into their component sounds or letters; integrate sounds or letters into words; write words of varying complexity from dictation; and read letters, words, phrases, and paragraphs.

Arithmetic skills. The subject is required to identify Arabic and Roman numerals, to identify the significance of digit placement, to compare numbers of varying size, and to perform simple arithmetic operations (multiplication, addition, subtraction) and simple algebraic manipulations. The ability to form arithmetic series is also evaluated. Items are presented both orally and visually.

¹ Due to time limitations and the desire to allow each article to be independently read, the present article reproduces some material from the previous article (Golden, Hammeke, & Purisch, 1978) on the standardized Luria test battery.

Mnemonic processes. The tasks assess an individual's retention and retrieval skills for visual, acoustic, and kinesthetic inputs. Items involve both verbal and nonverbal material. The effects of retroactive and proactive interference are also examined.

Intellectual processes. The final section requires the subject to interpret the themes of pictures, to demonstrate vocabulary skills, to form concepts, to classify objects, to understand analogies, to understand complex arithmetical problems, and to show logical reasoning skills.

The battery requires several pieces of inexpensive equipment. First, a series of cards with pictures and word items published by Christensen (1975c) are needed. Several additional pictures are necessary to replace some of the Christensen items that were found to be confusing for an American population. In addition, the battery requires (a) a 13-cm black comb; (b) a $2\frac{1}{4} \times \frac{1}{4}$ inch ($5.5 \times .6$ cm) rubberband; (c) a paper clip, jumbo size; (d) a Box Compass 5178 (available from Empire Pencil Company, Shelby, Tennessee 37160); (e) a Pedigree Quality Eraser 2910 (also available from the Empire Pencil Company); (f) a key (WR2 Curtis 177); (g) a straight pin; (h) a quarter; (i) a metric ruler; (j) an audiotape for some of the rhythm and verbal items; and (k) a blindfold.

Procedure

In the case of each potential subject, written permission was obtained to review medical records in order to assess whether the subject met the requirements of a confirmed diagnosis for the study. An individual whose diagnosis was questionable as to the presence or absence of brain injury was not included unless a definitive diagnosis was later established.

Once a patient had consented to participate, administration was arranged at a time that did not interfere with the hospital schedule. The majority of the test administrations occurred at bedside, although free rooms for testing were occasionally available. Because of the relatively short time needed to administer the battery, most of the testing was done in a single session. In some cases, however, the session was interrupted by visitors or medical tests.

Scoring. Items were scored by a variety of methods according to the nature of the item and the qualitative dimension that was being assessed. These scoring methods included accuracy of response, frequency of response, adequacy of response, number of errors, time for performance, trials to correct performance, and number of items completed. For many items, more than one scoring method was used to measure different performance dimensions.

All raw scores were recoded into a 3-point (0, 1, 2) scaled score. A scaled score of 0 was intended to represent the performance characteristic of a normal individual. A scaled score of 1 represented

an intermediate level of performance seen in both brain-injured and normal individuals. A scaled score of 2 represented the performance characteristic of brain-injured subjects. The scoring for each item was established by examining the performance of a mixed diagnostic group of 75 subjects collected in the first stages of this project.

Summary scoring indices. The scores of the items in each section were summed to yield a summary index for that function. Ten summary indices were created in this manner.

Four additional scoring indices were also created. The first measure summed the 34 most effective indicators of brain damage. These were items that when scored as 2, were nearly always indicative of brain damage. These items were selected on the basis of the performance of a mixed neurological, schizophrenic, and normal population collected during the development of the battery (Golden et al., 1978). This index was labeled the *pathognomic* index.

The second index was the sum of all items that required right-hand motor or tactile/kinesthetic function. The third index was similarly devised for all left-hand items. These indices were labeled *left hemisphere* and *right hemisphere*, respectively.

The final index represented overall performance. The scores on each of the 13 previous summary indices were converted into *z* scores using the means and standard deviations of data previously collected on a hospitalized normal control group. These 13 *z* scores were then summed into a final index, labeled a *total* score.

Results

Two-tailed *t* tests were computed for the scaled scores on all 282 measures between the schizophrenic and brain-injured groups. Of the 282 comparisons, the schizophrenics performed significantly better on 72 items at the .05 level ($df = 98$). The brain-injured group demonstrated better performance on 2 items at the .05 level of significance ($df = 98$). Using a stepwise discriminant analysis of the individual items, it was found that a hit rate of 100% could be achieved with 40 items.

The means and standard deviations were calculated for each of the 14 summary indices. Differences between the two groups were then determined by the two-tailed *t* tests, as reported in Table 3. The schizophrenics performed significantly better than the brain-injured subjects at the .01 level on 9 of the indices and at the .001 level on 1 other index. Four indices failed to significantly discriminate between the groups.

nation of indices was able to discriminate at an overall hit rate of 88%

Discussion

The results of this study demonstrate a high effectiveness for the standardized battery in discriminating between schizophrenia and brain injury. No other test or set of tests reported in the literature have achieved a comparable 100% hit rate. The 88% hit rate using the 14 summary indices is also higher than the results reported in any comparable studies. Most of the positive results reported for other tests were obtained using schizophrenic populations of slight to moderate chronicity compared to the long-term chronic schizophrenics used in this study.

Summary indices were devised to make the test easier to interpret with individual patients. Of the 14 indices, only the rhythm, impressive speech, memory, and intelligence summary measures did not significantly discriminate between the groups. The schizophrenic group performed in the brain-damaged range on these four scales, compared to a previously tested normal group (Golden et al., 1978). The acoustico-motor items required greater sustained concentration and attention than other items, which could have resulted in difficulties for schizophrenics, who found it hard to maintain this focus. The memory index included many interference tasks that may have triggered irrelevant interfering associations. The intellectual index, assessing higher abstract thinking and verbal-reasoning abilities, and the impressive speech index, which is disproportionately weighted with items presenting complex verbal relationships, were relatively difficult for the schizophrenics compared to the more basic indices.

On the other hand, schizophrenics demonstrated superior performance on the motor, tactile, visual, left-hemisphere, and right-hemisphere indices. Similarly, most of the items from other indices on which schizophrenics performed better than the brain-injured patients did not require complex symbolic manipulations, sustained attention, or higher abstract ability. These results are con-

sistent with the theoretical position that neurological damage results in impaired functioning for both simple and complex tasks, whereas cognitive impairment associated with schizophrenia results in greater disruption on tasks requiring complex verbal abilities than on tasks requiring little verbal mediation.

The hit rates obtained for each of the 14 indices demonstrate a 10%-20% decrease in diagnostic accuracy compared to the results obtained using hospitalized normal controls. It is clear that none of these indices used alone would be diagnostically accurate with long-term chronic schizophrenics. Nevertheless, these results are equal to or better than those found for other tests in similar populations. In addition, the 88% hit rate obtained is comparable to the 93% with the hospitalized normal controls (Hammeke et al., in press). This result underscores the necessity of considering all indices in determining differential diagnoses between long-term chronic schizophrenic and brain-injured patients.

The ability to comprehensively assess neuropsychological functioning in relatively little time is one of the major advantages of the battery. Yet, the development of effective summary measures from the rich item pool may further shorten administration time when there are specific diagnostic questions. For example, an index comprised of items chosen for their sensitivity to the general effects of brain damage could be developed as a simple screening device when there is a general question of presence or absence of brain damage. Indices used to answer other questions can be developed in a similar manner.

In addition to its clinical usefulness, the battery also shows good research potential. Unlike most other tests, the scoring of many items reflects a single qualitative dimension of a response, allowing component neuropsychological abilities to be more easily isolated and analyzed. Empirical relationships can be easily established between specific neuropsychological deficits associated with specific neurological disorders, with schizophrenia, and with such variables as medication and prognosis.

Overall, the results demonstrated that the standardized battery is able to make the difficult discrimination between long-term chronic schizophrenics and brain-injured patients. The battery's main advantages are short administration time, comprehensiveness, and a systematic breakdown of complex neuropsychological abilities. These features make the battery particularly well suited both for use as a research instrument in clarifying many of the presently unanswered questions about the underlying processes of schizophrenia and as a clinical tool for the neurodiagnostician working with schizophrenic and brain-injured patients.

Self-Administered Relaxation Training and Money Deposits in the Treatment of Recurrent Anxiety

Clifford E. Lewis, Anthony Biglan, and Elizabeth Steinbock
University of Oregon

This study evaluated two self-administered relaxation manuals and a money deposit in the treatment of recurrent, nonphobic anxiety in a college population. Subjects were randomly assigned to a self-monitoring-only control group or one of four active treatment conditions. Subjects in active conditions received a progressive relaxation manual or a manual that called for the client to devise his or her own relaxation method and were assigned to deposit or nondeposit conditions. Improvement did not differ for the two relaxation procedures, but relaxation training groups improved significantly more than self-monitoring-only subjects on both self-report questionnaires and self-monitored measures of anxiety. The money deposit did not produce greater amounts of relaxation practice or adherence to the program, although subjects in the money deposit condition did report being more relaxed in practice sessions and improved more on two pre-post measures of anxiety. Subjects' locus of control scores were significantly related to a number of practice, adherence, and outcome variables, but subjects' ratings of the likelihood that they would practice and benefit from the program proved to be as good predictors. The study suggests the value of self-monitoring and relaxation practice as treatment for recurrent, nonphobic anxiety.

Although considerable progress has been made in our ability to treat phobias (cf. Bandura, 1969; Kazdin & Wilcoxon, 1976; Paul, 1969), we have not yet identified an effective strategy for treating nonphobic, anxious clients. Despite the large number of phobic treatment studies, there have been surprisingly few systematic investigations of how we might effectively assist clients who

experience recurrent anxiety for which no stimuli can be identified or for which stimuli are too numerous to allow the use of phobic treatment procedures. In this study, we evaluated two forms of self-administered relaxation training as treatments for recurring, nonphobic anxiety in a college population and examined whether a money deposit increases the number of practice sessions that clients complete.

This study was supported by Grant MH27559-01 from the National Institute of Mental Health. It is based on a doctoral dissertation conducted by the first author, was supervised by Gerald Kranzler, and was submitted to the Department of Counseling of the University of Oregon.

Clifford Lewis is now at the Department of Rehabilitation, State of California.

Elizabeth Steinbock is now at Developmental Evaluation Clinic, Duke University Medical Center, Durham, North Carolina.

We appreciate the assistance of Richard Haller and Jennifer Scheetz.

Requests for reprints should be sent to Anthony Biglan, Department of Psychology, University of Oregon, Eugene, Oregon 97403.

Perhaps the most promising approach to nonphobic anxiety involves the use of some form of relaxation training. There is evidence from case studies that relaxation can benefit chronically anxious persons (Dawley, 1975; Raskin, Johnson, & Rondestvedt, 1973). Sherman's work (Sherman, 1975; Sherman & Plummer, 1973) suggests that persons can be taught to continue to use relaxation in stressful situations. Both Zeisset (1968) and Goldfried and Trier (1974) have presented evidence that relaxing as an active "coping skill" is beneficial at least for situationally specific anxieties. Thus, a program of relaxa-

tion training with instructions to relax in problematic situations could be an effective strategy for treating persons who suffer from recurrent, nonphobic anxiety.

It may not be necessary, however, to use the progressive or deep muscle relaxation procedure in such a program. It is possible that any procedure that helps clients interrupt chains of anxious responses will benefit them. Numerous responses other than deep muscle relaxation have been shown to reduce anxiety, including oriental defense exercises (Gershman & Stedman, 1971), muscle tension (Wolpin & Raines, 1966), and meditative procedures (Benson, Beary, & Carol, 1974). Kass, Rogers, and Feldman (1973) reported success in six of seven desensitization cases in which clients used anxiety-inhibiting responses that were already in their repertoires. This approach could be better than progressive relaxation training, since its instructions are simplified and subjects may be more likely to continue to use the techniques after treatment. In the present study, we examined whether persons who suffer from recurrent anxiety can achieve improvement simply through a self-administered program that instructs them to develop their own method of getting relaxed at regular practice sessions.

Perhaps the major problem in using self-administered materials is the lack of client adherence to the program (Glasgow & Rosen, 1978). In Rosen, Glasgow, and Barrera's (1976) study of self-administered desensitization of snake phobias, less than half of the subjects in self-administered conditions completed half of their hierarchies, and the number of program steps completed was highly correlated with a variety of outcome measures. Thus, getting subjects to continue working on self-administered programs may increase their effectiveness.

Money deposits have been used extensively as a method of achieving compliance with particular aspects of treatment programs. Deposits have been found to be effective in getting clients to keep appointments (Grove & Fredricks, Note 1), lose weight (Hall, 1972), continue in treatment (Bellack, 1976; Bellack, Schwartz, & Rozensky, 1974; Ha-

gen, Foreyt, & Durham, 1976), and adhere to program procedures (Eyberg & Johnson, 1974). We could find no studies that evaluated the effects of a money deposit on persistence in a self-administered program. Therefore, we experimentally evaluated whether a money deposit would increase clients' practicing in the two self-administered relaxation programs that we wished to evaluate.

Finally, it would be useful to establish client characteristics that are associated with successful use of self-administered programs. One often-cited variable, locus of control (Rotter, 1966), has been suggested as a predictor of program adherence and outcome (Abramson, 1973; Balch & Ross, 1975; Friedman & Dies, 1974; Mahoney & Thoresen, 1974). In addition to the possibilities of prediction from locus of control, it may be that clients can predict their own success directly (cf. McReynolds & Stegman, 1976). A straightforward approach to the problem of predicting adherence, such as ratings of the likelihood that they will comply with instructions, may be the best and cheapest method of selecting those who will use a self-administered program successfully.

In summary, this study evaluates the effectiveness of two self-administered manuals for relaxation training as treatments for recurrent anxiety. The manuals are evaluated in comparison with a self-monitoring control condition. The usefulness of a money deposit in achieving program adherence and anxiety reduction is also evaluated. Finally, locus of control and clients' own predictions are evaluated as predictors of program adherence and outcome.

Method

Subjects

Subjects were recruited from the University of Oregon and a nearby community college. The project was described as offering treatment for anxiety and tension. At initial phone contact, 12 persons declined to participate, and 3 additional persons declined to participate at the first appointment. Among the remaining 61 subjects who entered the study, there were 38 females and 23 males. They ranged in age from 18 to 44 years, with a mean of 24 and a mode of 20 years.

Interventions

During the initial interview subjects were instructed on methods of self-monitoring their anxiety. Following a week of self-monitoring, subjects were randomly assigned to one of five conditions. Assignments were done separately for men and women in order to equate the proportion of men and women in each condition.

Self-administered progressive relaxation. Subjects in this condition received a manual on deep muscle relaxation, which was written by Rosen (1975, 1976). The manual contained complete instructions for learning to relax. In addition, it described methods of becoming able to relax in tension-arousing situations. The manual suggested that the client practice each day in two 15 to 20-minute sessions.

Self-administered progressive relaxation plus money deposit. Subjects in this condition received the Rosen manual and were asked to deposit an amount of money that they "wouldn't want to lose." The return of 25% of the deposit was contingent on subjects' returning their daily practice log, their self-monitoring records and a mail in questionnaire (see below). The remaining 75% of the deposit was returned contingent upon the subject's completing a minimum of 15 practice sessions. The manual recommends 42 sessions.

Client-directed relaxation. Subjects in this condition were given a two-page manual. The manual suggested that "practicing relating itself, regardless of the method . . . is the key element in feeling more relaxed and at ease." Subjects were asked to take the time to practice getting as relaxed as they could in two 15 to 20 minute sessions each day, using any method that they found effective. These subjects were also instructed to try to learn to become relaxed in the same way when anxiety-producing situations arise in real life.

Client-directed relaxation plus money deposit. Subjects in this condition received the manual just described and in addition were asked to put up a money deposit (identical to that for subjects in the self-administered progressive relaxation plus money deposit condition).

Self-monitoring. Subjects in this condition were asked to continue monitoring their daily anxiety experiences for an additional 2 weeks. In addition, they were reminded that there is evidence that self-monitoring helps some people change their behavior.

Instruments

Pre-treatment and post-treatment anxiety measures. During the initial interview all subjects completed the Spaulding State-Trait Anxiety Inventory and an assessment questionnaire that was devised for the purposes of this study. The State-Trait Anxiety Inventory (Spaulding, Gorsuch & Luthene, 1970) consists of two 20-item scales. The first is designed to measure respondents' anxiety at that moment,

and the second is designed to measure the respondents' tendency to be anxious in general. The pre-treatment assessment questionnaire asked subjects about previous experience with relaxation training, the importance of learning to relax, and the amount of therapist time that they would ideally like to have in learning to relax. They were then asked to list three situations that occurred at least once each week and during which they would like to be more relaxed. They rated their comfort in each of these situations at its most recent occurrence. Finally, the questionnaire asked them to rate the extent to which they believed that they could learn to relax using an entirely self-administered program. All ratings were done on 7-point scales.

The State-Trait Anxiety Inventory was administered at posttest, 3 weeks following the initial interview at the same time, and under the same circumstances as had existed at pretest. A postassessment questionnaire was also administered. It asked subjects to rate (a) their ability to relax, (b) their sense of self-control, (c) the benefit that they felt they had derived from the program, and (d) the likelihood that they would use the techniques that they had learned for relaxing in the future. Finally, subjects rated their comfort during the most recent occurrence of each of the three situations that they had specified at pretest.

Internal-external Locus of Control (I-E) Scale. A modified version of the I-E scale (Rotter, 1966) was administered at the initial session and at post-testing (Cohen, Rothbart, & Phillips, 1976). The scale was administered at posttest to determine whether outcome in the relaxation program was associated with changes in locus of control.

Self-monitoring. During the intake interview subjects were asked to identify two situations in which they experienced anxiety. One of the designated situations (Situation A) must have occurred daily. The second situation was one that occurred at least 3 times each week (Situation B). Clients were given pocket-size booklets and were instructed to record the occurrence of Situations A and B, their tension levels in these situations, and any other occurrences of tension. Ratings of tension were done on a 100-point scale, where 0 indicated no discomfort and 100 indicated the most extreme tension that the person had ever experienced. Subjects were also asked to rate their tension level for the entire day and to estimate the frequency of feeling tense during the day. All subjects continued self-monitoring for the entire 3 weeks of the program.

Expectancy questionnaire. Subjects who received relaxation instructions were asked to rate their expectations regarding the program immediately after they had read their relaxation instructions. They were asked to rate (a) how likely they thought the program would enable them to get relaxed, (b) how likely they thought they would do the prac-

¹ Copies of this manual are available from the second author.

sion sessions, and (c) how easy they thought it would be to follow the program. Ratings were made on 7-point scales.

Daily practice log. Subjects who received the relaxation instructions were asked to record the date, time, and length of each practice session, and were asked to rate on 10-point scales how easy it was to get relaxed and how relaxed they actually became.

Procedure

Subjects were seen on three occasions. During the first appointment the study was described and the subject was asked to read and sign a statement of informed consent. During this session, subjects filled out all pretreatment assessment instruments, were assisted in identifying situations that made them anxious (Situations A and B), and were given instructions on self-monitoring their anxiety. After 1 week of self-monitoring, subjects returned to the clinic and met with the experimenter. At this time subjects in the active treatment conditions were given relaxation manuals, and those in the deposit condition were asked to put up an amount of money that they "would not want to lose" (Grove & Fredricks, Note 1). Subjects in the relaxation conditions also received the expectancy questionnaire and practice logs. Those in the self-monitoring-only condition simply received further self-monitoring materials and were reminded that self-monitoring could help them to reduce anxiety. The third session occurred following 2 weeks of relaxation practice. At this time subjects were asked to complete the posttreatment instruments as described above. Subjects who had been in the self-monitoring-only condition received copies of the Rosen manual and instructions for its use at this session.

The amount of time that the experimenter spent with each subject was limited. The total time in which the experimenter was in contact with the subject over all three sessions was typically 1 hour and 40 minutes. The bulk of this time (approximately 60 minutes) was spent in subject's completing the relevant questionnaires. Thus, the procedures of this study approximate a wholly self-administered treatment program.

Results

Preliminary Analyses

Subjects' State Anxiety and Trait Anxiety scores were compared with published norms for these scales (Spielberger et al., 1970). On State Anxiety, this study's sample scored between the 73rd and 76th percentile for college undergraduates. For Trait Anxiety, the sample was at the 90th percentile. Comparisons with norms for clients seeking as-

sistance at a university counseling center indicated that the present sample was essentially equal to counseling center clients in State Anxiety and 6 points higher on Trait Anxiety. Of the 61 subjects, 39 had sought treatment previously. The mean length of time that clients had been anxious was 58 months.

As a check on randomization, one-way analyses of variance across the five treatments were conducted on all pretest measures. No significant differences were found (all $ps > .15$). One-way analyses of variance for sex differences at pretest and posttest were conducted as well as analyses of variance for the Sex \times Treatment Conditions interaction. For all but one measure, no sex-related differences were found (all $ps > .70$). The only significant sex-related difference was found for pretest and posttest locus of control scores (both $ps < .02$). Men scored significantly more internally than women, a difference that has been found by other investigators (Feather, 1968; Phares, 1976; Platt, Pomeranz, Eisenman, & DeLisser, 1970).

Statistical Analyses

Tests of the effects of the experimental manipulations were conducted by planned comparisons of change scores between pretesting and posttesting. These included (a) tests for differences between the two relaxation manuals; (b) tests for differences between the relaxation conditions and the self-monitoring-only condition; and (c) tests for differences between relaxation with money deposit and relaxation without a money deposit. These comparisons were made for both questionnaire anxiety measures and for self-monitored data. For self-monitored data, means were computed for Weeks 1 and 3, and change scores were derived by taking the differences between these means.

Note. STAI = State-Trait Anxiety Inventory; A-Trait = Anxiety Trait scale; A-State = Anxiety State scale.

parisons of progressive and client-devised relaxation revealed no significant differences on any of the self-monitored or pre-post measures of anxiety. However, subjects who received progressive relaxation did rate themselves as able to relax at will to a significantly greater extent than did subjects in the client-devised condition, $t(47) = 2.26$, $p < .05$ (two-tailed). The groups did not differ on rated expectations.

Relaxation training versus self-monitoring only. Planned comparisons between relaxation training and self-monitoring-only conditions revealed a number of significant differences. Subjects who received relaxation training were significantly more improved on three self-monitored variables. They evidenced greater improvement on the frequency of Situation B, $t(13.9) = 2.25$, $p < .025$,² the total frequency of all anxiety-arousing situations, $t(14.6) = 2.46$, $p < .025$, and end of the day estimates of the total frequency of anxiety-arousing situations, $t(19.8) = 2.22$, $p < .025$. At pretreatment and posttreatment assessment, subjects receiving relaxation training were significantly more improved than the self-monitoring-only subjects on (a) State Anxiety scores, $t(47) = 2.40$, $p < .01$; (b) ratings of the discomfort that they experienced in Situation A, $t(47) = 1.78$, $p < .05$; and (c) ratings of their discomfort in Situation B, $t(47) = 1.78$, $p < .05$.

Three additional problem situations were rated at pretreatment and posttreatment but were not monitored during the program period. These unmonitored situations may be viewed as measures of the generalization effect produced by treatment conditions. Changes in the ratings of these situations did not differ among active treatment conditions. However, subjects in active treatment conditions evidenced significantly greater improvement on their ratings of discomfort in these situations than did the self-monitoring-only group, $t(47) = 1.73$, $p < .05$, $t(47) = 2.44$, $p < .05$, and $t(47) = 2.01$, $p < .05$.

Effects of Money Deposit

Subjects in the money deposit condition had to participate in a minimum of 15 practice sessions to get 75% of their money back.

Subjects in this condition were asked to deposit an amount of money that they "would not want to lose." Amounts deposited ranged from \$.10 to \$50. The mean amount of money deposited was \$6.01, and the median was \$1.50.

Practice and program adherence. Subjects in deposit and nondeposit conditions did not differ in the total number of practice sessions or in the average length of practice sessions. An examination of the group means for length of practice session indicated that subjects in the progressive relaxation without money deposit and the client-devised relaxation with deposit conditions spent significantly more time in practice sessions than did subjects in the other two groups, $t(31) = 2.60$, $p < .01$. Subjects in relaxation conditions rated their depth of relaxation in each practice session as well as the ease with which they were able to relax. Those in the money deposit condition had significantly higher ratings on ease, $t(32) = 2.60$, $p < .01$, and depth of relaxation, $t(32) = 2.54$, $p < .01$, than did nondeposit subjects.

Program adherence was assessed in terms of the number of days on which subjects kept self-monitored records, the number of steps in the program that they completed, and the number of days that they remained in the program. Deposit and nondeposit subjects did not differ on any of these variables. Nor were there significant differences for the proportion of subjects in each condition who dropped out of the study.

Changes in anxiety measures. Subjects in the money deposit condition improved significantly more than nondeposit subjects on two of the self-monitored ratings of anxiety. Deposit subjects improved significantly more on their ratings of tension in Situations A and B, $t(33) = 1.82$, $p < .05$; $t(5.1) = 2.63$, $p < .05$. There were no differences between deposit and nondeposit conditions on any of the questionnaire anxiety assessments.

Relation of amount deposited to other variables. Finally, it was found that the amount of money that subjects in the de-

² When the Bartlett-Box F was significant, separate variance estimates and degrees of freedom were calculated.

posit condition put up was correlated with their rating of the importance of their learning to relax, $r(25) = .40$, $p < .05$, but was not related to any outcome or practice measures.

Predictors of Program Adherence, Practice, and Outcome

Adherence and practice. Locus of control was significantly correlated with the number of days on which subjects self-monitored their anxiety, $r(61) = -.30$, $p < .025$, and the number of steps that they completed in the program, $r(61) = -.34$, $p < .025$. Locus of control was also significantly correlated with the number of days that the subject remained in the program, $r(61) = -.29$, $p < .025$. All of the correlations were in the direction of "internals" showing greater program adherence. Locus of control scores were not significantly related to practice variables such as number of relaxation sessions completed, length of practice sessions, or rated ease and depth of relaxation.

Subjects rated their expectations that they would (a) be able to learn to relax using the program, (b) do the practice sessions, and (c) find it easy to follow the program. These ratings were significantly correlated with both adherence and practice variables. With respect to adherence, subjects who predicted that the program would enable them to relax kept self-monitored records for more days, $r(43) = .38$, $p < .006$, and those who predicted that they would do the practice sessions kept self-monitored records for more days, $r(43) = .48$, $p < .001$, completed more steps of the program, $r(43) = .39$, $p < .005$, and remained in the program longer, $r(43) = .44$, $p < .002$. With respect to practice, it was found that subjects' ratings of the likelihood that they would practice were significantly correlated with the number of practice sessions that they completed, $r(43) = .45$, $p < .001$. Moreover, subjects who believed that the program would help them relax had significantly greater ease in relaxing, $r(36) = .38$, $p < .05$.

Outcome measures. The relationship of outcome to locus of control was evaluated by correlating locus of control scores with sub-

jects' change scores on the four pre-post anxiety measures and the seven self-monitor variables. Significant relationships were found for three variables. Those scoring in the internal direction on locus of control showed greater reduction in trait anxiety, $r(52) = -.28$, $p < .02$, and on self-monitored data they showed greater reductions in the total number of times that they were anxious per day, $r(42) = .27$, $p < .04$, and their end of day rating of tension, $r(43) = .30$, $p < .025$.

A similar analysis was conducted to determine whether subjects with high expectations for the program improved significantly more than subjects whose expectations were low. Subjects who predicted that the relaxation program would enable them to relax were significantly more improved on state, $r(40) = .50$, $p < .001$, and trait, $r(40) = .40$, $p < .006$, anxiety and on their daily rating of tension, $r(34) = .29$, $p < .05$. No other correlations were significant.

Program Adherence as a Predictor of Outcome

Finally, analyses were conducted to determine whether program adherence variables were related to outcome. No significant results were found. Differences among subjects in the number of steps that they completed in the program, the length and number of their relaxation practice sessions, their rated ease and depth of relaxation during these sessions, and the number of days on which they completed self-monitoring records were not related to any pre-post or self-monitored anxiety measures.

Discussion

The results of this study suggest that self-administered relaxation training, when combined with self-monitoring, can be of significant benefit to persons who suffer from recurring anxiety. Moreover, since few differences were found between progressive and client-devised relaxation groups, it appears that extensive, structured training in progressive relaxation is not necessary to achieve these benefits. Even though relaxation groups were superior to the self-monitoring-only condition, it should be noted that the latter

condition could itself be considered an active treatment. Indeed, clients in this condition improved on four of the seven self-monitored measures and on three of the four pre-post anxiety measures. Three of these improvements were statistically significant. This is consistent with other evidence in the literature that self-monitoring can produce changes in behavior (Nelson, Lipinski, & Black, 1975; Richards, McReynolds, Holt, & Sexton, 1976).

The improvements of the self-monitoring-only subjects also suggest that the beneficial effects of the relaxation conditions were dependent, in part, on these subjects' self-monitoring of anxiety. Relaxation training may not be of benefit in the absence of self-monitoring.

In both sets of relaxation training materials, subjects were explicitly instructed to attempt to actively use their relaxation when they began to feel anxious. Although it was not experimentally evaluated in the present study, this instruction may have been essential to the success of the program. The fact that relaxation subjects were significantly more improved than self-monitoring-only subjects in the unmonitored anxiety-arousing situations suggests that relaxation subjects were able to generalize the relaxation responses that they were learning to a variety of problematic situations.

It should be remembered that subjects in this study were college students. Although comparison with available norms suggests that they were moderately to highly anxious, the results of this study may not generalize to a more severe population such as chronically anxious outpatients in a clinical setting.

Although subjects in the relaxation training groups improved significantly more than those in the self-monitoring-only control condition, intersubject variability in improvement was quite high on many of the variables. Thus, even though the present findings point to the value of further developing relaxation treatments for recurrent anxiety, they do not represent clinically significant improvements for all relaxation subjects. One strategy for treating anxious clients would be to have a variety of techniques available.

The relaxation technique that has proven effective for the greatest number of people could be used first, but in the event that the first intervention was not successful, additional procedures should be available.

This study provides only limited support for the use of money deposits in self-administered programs. Despite the fact that the return of 75% of the money deposit was contingent on subjects' completing 15 or more relaxation practice sessions, money deposit groups did not practice significantly more than nondeposit groups. In fact, the mean number of practice sessions for deposit conditions was less than 15, which was lower than the comparable nondeposit conditions. Subjects who deposited money did rate the ease and depth of relaxation in practice sessions higher than did nondeposit subjects, but these results may be due to a nonsignificantly higher dropout rate among deposit subjects. Similarly, differential dropout may account for the few outcome differences that favored the nondeposit condition.

It would be premature, however, to completely abandon the use of money deposits in self-administered programs. Most subjects in the deposit condition put up very small amounts of money. The mean deposit was only \$6.01, and only six subjects put up 10 or more dollars. In a project to develop self-administered materials for depressed clients, we have generally found that persons seeking treatment put up larger amounts of money and generally do comply with our programs. Even though it is true that the amount of money deposited did not correlate with practice or outcome variables in this study, this result may be due to the fact that few subjects put up amounts of money that could have had an impact on their subsequent adherence to the program.

Our findings regarding the prediction of program success suggest the practical utility of simply asking people whether they think they will comply with and succeed in a self-administered program. The single rating of likelihood that subjects would complete the practice sessions was significantly related to the number of practice sessions completed as well as to all three measures of program ad-

herence. Similarly, the rating of the likelihood that the program would enable them to relax was significantly related to improvements on state anxiety and trait anxiety as well as daily tension ratings. Although locus of control scores were also related to program adherence measures and to three outcome measures, these relationships were less numerous and consistently less strong than those for the subjects' predictions about their own behavior. These results are consistent with the hypothesis that the I-E scale is itself measuring the extent to which people say that they will exert effort and can succeed on a variety of tasks. Thus, the scale need not be viewed as a measure of an internal, unitary construct. Rather it can be considered to assess the extent to which the people say, in a variety of ways, that their effort makes a difference. The scale's ability to predict success in self-administered programs may simply be due to the fact that working on a self-administered program is similar to the kinds of activities that the I-E scale asks about. Those who say that preparation makes the difference on a test will also say that they can use a self-administered program successfully. And, to some extent, these verbal responses are related to actual behavior (Skinner, 1957).

In concluding, we note several limitations of the present study that define some of the requirements for further research. First, the data were restricted to self-report questionnaires and self-monitoring. It is essential that we investigate whether such measures are accurately related to anxiety as it actually occurs in the daily life of clients. Second, the absence of relationship between program adherence and outcome variables leaves us unable to pinpoint the effective components of the relaxation treatment conditions. It would be useful to experimentally manipulate variables such as number of practice sessions and use of self-monitoring to elucidate their contribution to outcome. Finally, ratings of subject expectation for outcome were not obtained from self-monitoring-only subjects subsequent to their assignment to this condition. Since expectancy measures were related to outcome measures for subjects in relaxa-

tion conditions, it can be argued that the superiority of relaxation groups was more a matter of social influence than of the specific effects of relaxation and self-monitoring. It will be important in subsequent research to assess whether the self-monitoring condition does produce expectations for improvement that are comparable to those for relaxation conditions.

Goal Definition by Staff Consensus: A Contribution to the Planning, Delivery, and Evaluation of Mental Health Services

Theodore W. Lorei and Eugene M. Caffey, Jr.
Veterans Administration, Washington, D.C.

To provide a basis for the evaluation of the Veterans Administration mental health services, a survey was conducted of staff opinion regarding the importance of several specific goals for these services. Nine goals were formulated and submitted to 6,435 central office and field facility staff to obtain their ratings of the importance of each of these goals, with an "of no importance" rating being possible. The goals dealing with (a) the development of patient skills necessary for being self-supporting, (b) the elimination of psychological disorders, and (c) the protection of patients and others from violence received the highest average ratings. The remaining goals were considered as having some importance, although there were substantial differences among the sample about the degree of importance. Interoccupational group differences in importance ratings were statistically significant but small. Although the goals formulated and ratified by staff were quite general, they were much more specific than previous goal statements. Because of this relative specificity, they provide useful guidance for planning, managing, delivering, and evaluating mental health services.

More than 6,000 professional staff members are involved in planning and delivering mental health services in Veterans Administration (VA) hospitals and clinics, as well as in the national administrative office. To what extent do these people have a common understanding of the objectives of these services? To find out, we surveyed their opinions about nine carefully formulated goals describing the desired impact of mental health services on the well-being of patients and communities. The results, analyzed for the group as a whole and for six professional subgroups, are reported here.

The authors acknowledge the substantial contribution of Lee Gurel to the formulation of the goal statements, as well as the assistance of Jack Collier, Robert Normand, Jacqueline McEwan, Wanda McKinney, the hospital and clinic survey coordinators, and of all the Veterans Administration staff who completed the questionnaire.

Requests for reprints should be sent to Theodore W. Lorei, Veterans Administration, 810 Vermont Avenue, N.W., Washington, D.C. 20420.

The study was developed from a previous application of decision theory concepts to decisions about releasing patients from psychiatric hospitals (Lorei, 1970). This application involved the formulation of a set of brief statements describing the possible outcomes of releasing or retaining patients. The importance of attaining or avoiding these outcomes was rated by clinical and administrative staff in 13 hospitals. These ratings suggested that staff differed substantially in their underlying objectives. For several reasons that are discussed more thoroughly later, it seemed important to inquire about these underlying objectives directly.

The research reported is related to the work just described but differs in several important respects. First, the central objects of the study were *goals* rather than *outcomes*. (For our purposes the relationship between outcomes and goals is one in which a goal is defined as a positively valued outcome.) Second, we are concerned not with a specific set

of alternative acts (release or retention from a hospital) but with a complex program of activities—all mental health services provided by the VA. And finally, in establishing the importance of goals for these services, staff from the entire VA mental health system, including those in the national administrative office, were consulted.

Although our original interest in outcomes and goals derived from decision theory, literature from several other areas also stresses the importance of goal clarity. Examples of these areas include management theory (Raia, 1974), education (Mager, 1975), psychotherapy (Mahrer, 1967), behavior modification (Bandura, 1969), and program evaluation (Weiss, 1972). The reason for the emphasis is clear: Individuals and groups cannot successfully manage organizations, devise curricula, modify the behavior of others, or evaluate programs unless the goals motivating the managers, the educators, the behavior modifiers, and the program operators are clear. The administration of mental health services (their planning, implementation, and evaluation) should profit from the clarification of goals found essential in so many fields.

The research described here was intended to contribute to the clarification and specification of the goals of all major mental health services. Our strategy was simple: We formulated a provisional set of goals and then asked the operators of the VA mental health services what they thought of these goals. The questions we sought to answer were (a) How important did VA staff consider each of the nine goals presented? (b) What additional goals did staff suggest? (c) How much consensus was there about the importance of each goal? and (d) What fundamental value dimensions appear to determine the goal importance ratings?

Method

Sample

The target sample included staff both in the VA national administrative office and in all hospitals and free-standing clinics serving substantial numbers of psychiatric patients. The national office sample included staff with responsibilities for mental health

programs. The hospital and clinic target sample was designed to include two subsamples: (a) management staff—hospital (or clinic) director and assistant director; the chief and assistant chief of staff; and the chiefs and assistant chiefs of psychiatry, psychology, social work and nursing and (b) clinical staff—all physicians (usually psychiatrists), psychologists, social workers, nurses, rehabilitation medicine senior therapists, and chaplains who spent at least 50% of their time working with psychiatric patients.

Instrumentation

Nine goals were written by the first author on the basis of the previous research on staff opinions about possible outcomes of release from or retention in psychiatric hospitals, review of agency documents, and discussions with VA staff in both the national office and in the field. The formulations were guided by Hatry's (1970) advice that program goals should emphasize outputs (in this case, *effects on people*) rather than inputs, such as number of patients treated, services provided, and so forth. For example, a statement such as "involve more patients and families in family therapy programs" was not regarded as a goal. However, included in the list of goal statements was one possible result of such programs—"to minimize stress on families resulting from living with and/or being responsible for veterans with psychiatric disabilities." The nine goal statements were written in questionnaire format. In the first section, the respondent was asked to rate the importance of each goal on a 6-point category scale. In the second section, goals were presented in sets of three, and the respondent was asked to rank them in order of their importance. Using a computer program developed by Gulliksen and Tucker (1961), which made the computation feasible, an incomplete pair-comparison procedure was used to derive interval scale values. (Only the results of the rating procedure are reported here.)

Results

Total Staff Opinions about Goal Importance

The mean importance ratings for all staff combined are shown in Table 1. Scale points ranged from 0 (of no importance) to 5 (extremely important). Three goals received an average rating greater than 4 (of great importance)—(a) To develop the self-care, interpersonal, and work skills necessary for veterans to become or remain self-supporting in the community; (b) to eliminate or reduce disorders of perception and thinking, severe emotional distress, drug addiction, and

Table 1
*Mean Importance Ratings for Goals of Services
 for Psychiatrically Disabled Veterans*

Goal	M	SD
How important is it for the VA to:		
4. Develop the self-care, interpersonal, and work skills necessary for veterans to become or remain self-supporting in the community?	4.62	.69
5. Eliminate or reduce disorders of perception and thinking, severe emotional distress, drug addiction, and alcoholism?	4.37	.88
6. Minimize the chances that severely disturbed veterans will injure or kill themselves or others?	4.21	1.09
9. Minimize restriction of veterans' personal liberty by requiring hospitalization only when absolutely necessary?	3.89	1.20
8. Provide a sheltered environment for those veterans unable to live in the community without serious distress or damage to themselves?	3.61	1.17
1. Teach skills useful for living within an institution (self-care, work details, etc.) to those patients who will probably always require institutional care?	3.57	1.21
2. Provide enough money to live in the community for those veterans who are too disabled to work?	3.27	1.28
3. Minimize stress on families resulting from living with and/or being responsible for veterans with psychiatric disabilities?	3.26	1.20
7. Minimize the chances that veterans will be "public nuisances" by virtue of odd behavior, chronic drunkenness, disorderly conduct, vagrancy?	2.72	1.42

Note. $N = 6,435$. VA = Veterans Administration. Scale points were defined as follows: 0 = of no importance; 1 = slightly important; 2 = moderately important; 3 = quite important; 4 = of great importance; 5 = extremely important.

alcoholism; and (c) to minimize the chances that severely disturbed veterans will injure or kill themselves or others. Even the lowest rated goal, "to minimize the chances that veterans will be 'public nuisances,'" was

rated 2.72 (between moderately and quite important).

Additional Goals

An informal content analysis was made of additional goals that 17% of the respondents had proposed (as they were invited to do on the questionnaire). Practically all suggestions described means for achieving the goals presented, such as expanding outpatient programs, supporting community living, providing greater continuity of treatment, and removing the requirement that only disabilities resulting from military service can be treated. The few suggested goals were not substantially different from the original set.

Staff Consensus

Total group. An indication of the agreement among staff about the importance of each goal is given by the standard deviations in Table 1. Theoretically, the standard deviations could range from 0 (perfect consensus) to 6 (equal numbers in the two extreme categories of the scale). Judged on this scale, the degree of staff agreement about all goals was quite high. The small deviations, of course, indicate greater consensus; and, as would be expected, there was more agreement about the high-rated goals than there was about the others.

Occupational subgroups. The deviations of each of the means of the goal importance ratings for six occupational groups from the means for the total staff group are presented in Table 2. This presentation makes it easy to see, for example, that of the six occupational groups, physicians regarded the development of skills necessary for self-support (Goal 4) as less important than did psychologists.

As can be seen from the F values (one-way analysis of variance) in Table 2, the mean importance ratings varied significantly across groups for all goals except "eliminate psychological disorders." Although most of the differences were small, there were medium or close to medium sized differences for the following three goals: (a) to minimize the chances that veterans will be public nuisances

Table 2
*Mean Goal Importance Ratings for All Staff and Deviations of Means
 for Occupational Subgroups*

Goal	Grand M	Chaplain	Nurse	MD	Psychol- ogist	RMST	SW	η^a	F
4. Develop skills necessary for self-support	4.62	-.11	.05	-.14	.10	.04	-.05	.12	17.64*
5. Eliminate psychological disorders	4.37	.07	.01	-.06	-.06	.08	.02	.05	2.78
6. Minimize chances of violence to self or others	4.21	.08	.16	.01	-.52	.03	-.13	.19	46.85*
9. Minimize restrictions on personal liberty	3.89	-.31	.20	-.33	.04	-.17	-.02	.17	38.51*
8. Provide a sheltered environment	3.61	.03	.09	-.12	-.36	.15	.05	.13	20.22*
1. Teach skills for institutional living	3.57	.15	.26	-.19	-.43	.27	-.35	.24	74.20*
2. Provide money	3.27	.16	.01	-.18	-.37	-.06	.40	.17	37.91*
3. Minimize family stress	3.26	.11	-.02	-.19	-.34	-.07	.49	.20	54.10*
7. Minimize chances that veterans will be "public nuisances"	2.72	.26	.23	.02	-.84	-.35	-.33	.25	84.44*

Note. $N = 6,292$. RMST = rehabilitation medicine senior therapists; SW = social workers. Scale points were defined as follows: 0 = of no importance; 1 = slightly important; 2 = moderately important; 3 = quite important; 4 = of great importance; 5 = extremely important.

^a Values of .10, .24, and .37 may be regarded as indicating small, medium, and large differences among occupational groups, respectively (Cohen, 1969).

* $p < .01$.

by virtue of odd behavior, chronic drunkenness, disorderly conduct, vagrancy; (b) to teach skills useful for living within an institution (self-care, work details, etc.) to those patients who will probably always require institutional care; and (c) to minimize stress on families resulting from living with or being responsible for veterans with psychiatric disabilities. Table 1 shows that these goals also had three of the highest standard deviations (measures of disagreement) for the total group.

Facilities. The mean goal importance ratings for the total staff group at each facility (hospitals and clinics) differed at a statistically significant ($p < .01$) level for all goals except "to eliminate psychological disorders," but, practically, these differences were small. There was most interfacility variation regarding the importance of minimizing restrictions on personal liberty and minimizing

chances that veterans will be public nuisances."

Value Determinants of Goal Importance Ratings

Although the nine goals were written to deal with relatively independent issues, it was apparent that there were interrelationships among them. To explore the possibility that some more general value orientations might underlie the way staff rated the importance of the nine goals, these goals were intercorrelated and factor analyzed. The varimax factor structure appears in Table 3.

Factor 1 is defined by a special concern with minimizing the chances of violent behavior and other behavior that would constitute a public nuisance. Factor 2 is characterized by attaching importance to minimizing family stress and providing money for

Table 3
Varimax Factor Structure

Goal	Factor				
	1	2	3	4	5
1. Teach skills for institutional living	.21	.11	.44	.11	.15
2. Provide money	.07	.48	.28	.08	.18
3. Minimize family stress	.16	.52	.08	.13	.09
4. Develop skills necessary for self-support	-.08	.06	.14	.47	.27
5. Eliminate psychological disorders	.25	.15	.03	.51	.04
6. Minimize chances of violence to self or others	.68	.09	.19	.11	.07
7. Minimize chances that veterans will be "public nuisances"	.54	.29	.32	.04	.00
8. Provide a sheltered environment	.31	.29	.50	.09	.07
9. Minimize restrictions on personal liberty	.05	.13	.09	.13	.42

Note. $N = 6,435$. This factor structure was obtained by rotating five principal factors extracted from a correlation matrix in which squared multiple correlations had been entered as communality estimates. The number of factors selected for rotation was suggested by examination of the latent roots.

disabled veterans to live in the community. Factor 3 emphasizes the importance of (a) providing a sheltered environment to patients, (b) teaching skills useful for institutional living to patients with poor prognoses, and (c) minimizing the chances that patients will be public nuisances. These goals have usually been termed *custodial*. Factor 4 is defined by the two goals dealing directly with patient change, one with the development of positive skills and the other with the elimination of psychopathology. These objectives can be considered as comprising what is usually considered a "treatment" ideology. Finally, Factor 5, defined by one goal, deals with the protection of patient liberties.

Discussion

It is unquestionably difficult to ascertain precisely the goals of people for either their personal or professional activities. As Quade (1975) has noted,

In stating objectives, officials do not always reveal what they really want, sometimes because they feel they must maintain a position or front, sometimes because it might mean loss of support, sometimes (maybe most often) because they don't know what they want (p. 86)

We suspect that this observation may have applied to some of our respondents. And even if they always had a clear conception of their goals (an unlikely supposition), it probably would be hard in many cases to express them on the brief instrument used. Nevertheless, having acknowledged these problems, we feel that our results provide at least a first approximation of the goals of VA staff for the mental health services that they provide.

The results suggest that a large proportion of staff considered the nine goals important, although their degree of importance varied considerably. Goals for producing patient change took precedence over those concerned with the welfare of relatives or others in the community and over those that implied acquiescence to permanent disability (such as teaching skills useful for institutional living). The most important objective involved making patients self-supporting, a position consistent with Jahoda's (1958) statement:

One value in American culture compatible with most approaches to a definition of positive mental health appears to be this: An individual should be able to stand on his own two feet without making undue demands or impositions on others. (p. xi)

The same value probably accounts for the

importance attached to teaching skills useful for institutional living. Even though to be institutionalized is to be dependent, there might be some opportunity for even an institutionalized person to "stand on his own two feet."

In addition to determining whether the goals that we formulated were considered important by staff, we were interested in the degree of staff consensus about goal importance. This interest derived from a perspective that has been well stated by Tawney (1926), writing in an entirely different context. He stated that

For the condition of effective action in a complex civilization is cooperation. And the condition of cooperation is agreement, both as to ends to which effort should be applied, and the criteria by which its success is to be judged. (p. 232)

The survey results suggest that agreement about the ends to which effort should be applied is fairly high. However, the generality of the goals may exaggerate the appearance of consensus. Some suggestion that this occurs is provided by studies by Prothro and Grigg (1960) and by McClosky (1964) that people's agreement with social issues is greater the more abstract the issue.

If the generality of the goal statement does mask important differences of opinion among staff, attention should be paid to even small indications of staff disagreement. For instance, the fact that psychologists rated seven of the nine goals as less important than did other occupational groups may point to important differences in values. Multidisciplinary discussion of these differences and of the special "preoccupations" of each profession—such as teaching institutional skills (nurses), developing independence (psychologists), and providing money (social workers)—might improve communication and strengthen commitment to common goals.

Although the nine goals are more specific than traditional "goals," such as providing treatment, rehabilitation, care, and custody, the process of specification needs to be continued. For example, the meaning of being "self-supporting" needs to be further clarified as to the prerequisite self-care, interpersonal, and work skills. Considerable guidance

could be obtained from educational literature on formulating instructional objectives. Mager (1975), for example, gives the following illustration: "Given a compass, ruler, and paper, [the student should] be able to construct and bisect any given angle larger than five degrees. Bisections must be accurate to one degree" (p. 79). This example includes a description of the behavior that is to occur as a result of instruction, the conditions under which it is to occur, and the standard of performance that is to be met. Such thinking seems to be directly translatable to the behavior that patients should manifest (or not) as a result of treatment.¹

Finally, it is probably worth noting that a commitment to clarifying the goals of mental health services does not imply preference for any particular paradigm for conceptualizing abnormal behavior, for example, medical model, psychoanalytic, or behavioristic. The focus of concern about goal clarity is on the end product of treatment and not the intermediate conditions (such as development of insight) for achieving it. Perhaps the greatest contribution of the goal-oriented approach is that it provides a common framework for communications among people of diverse professional and theoretical positions.

¹ Although space limitations prevent describing our applications of the results of the goal-setting process reported here to the evaluation of day hospitals, day treatment centers, and drug-dependence treatment centers, further information can be obtained from the first author.

Comparison of Electromyographic Feedback and Progressive Relaxation Training in Treating Circumscribed Anxiety Stress Reactions

Martha P. Miller
University of Oklahoma

Philip J. Murphy
Oklahoma State University

Terry P. Miller
Stillwater, Oklahoma

This study examined the effects of electromyographic (EMG) feedback and progressive relaxation training on the anxiety stress reactions of patients having recurrent, negative reactions to dental treatment. Twenty-one subjects selected from the patient files of one dentist were randomly assigned to one of three groups: EMG feedback, progressive relaxation, or control. Four dependent measures, EMG level, Dental Anxiety Scale (DAS), and State-Trait Anxiety Inventory (A-State and A-Trait), were collected at prerelaxation and postrelaxation training dental appointments. Results showed significant, comparable decreases in EMG levels across dental appointments for both EMG feedback and progressive relaxation groups but not for the control group. On the DAS and A-State measures, significant decreases in all groups were found. Although the decreases shown by the EMG feedback and progressive relaxation groups did not differ significantly from each other, they were both significantly greater than the decrease shown by the control group.

Even though human reaction to stress has been the focus of much psychological investigation, there is little research in the area that has been carried out under natural, stress-provoking conditions. Lazarus (1966) has noted that the dental context provides an excellent area in which to study both physiological and psychological aspects of stress. Due to the nature of the procedures involved, anxiety stress reactions are experienced by many patients undergoing dental treatment. The dental setting thus provides the opportunity to study firsthand the effectiveness of psychotherapeutic techniques aimed at relieving stress reactions.

Relaxation of the body musculature has

been suggested as one means by which anxiety stress reactions can be reduced (Jacobson, 1938; Shultz & Luthe, 1959; Wolpe, 1958). Emphasizing the important role of relaxation in treating a number of stress-related disorders including anxiety states, Jacobson (1938) developed a verbal technique (progressive relaxation) designed to systematically train individuals to relax. More recently, relaxation training using electromyographic (EMG) feedback has been suggested as a way to reduce anxiety stress reactions (Budzynski & Stoyva, 1969; Green, Green, & Walters, 1973).

Several studies have dealt with whether muscular relaxation learned through progressive relaxation training leads to the reduction of anxiety. Comparing the effects of progressive relaxation and hypnosis, Paul (1969) found that anxiety indicators in normal subjects were reduced significantly in the relaxation group in contrast to the hypnosis and control groups. Partial substantiation of the relaxation training-anxiety reduction

This article is based on a dissertation submitted by the first author to the University of Oklahoma in partial fulfillment of the requirements for the PhD degree.

Requests for reprints should be sent to Martha P. Miller, who is currently in the private practice of psychology at 4900 North Portland, Suite 112, Oklahoma City, Oklahoma 73112.

hypothesis was shown in studies by Wilson and Wilson (1970) and Connor (1974). In the former study, only the high-anxiety relaxation group showed significant decreases in anxiety indicators, whereas in the latter study, the relaxation group showed reductions in physiological (but not self-report) stress indicators. Although progressive relaxation has long been held to be an effective treatment for reduction of anxiety stress reactions (Haugen, Dixon, & Dickel, 1958; Jacobson, 1938, 1970), little research has been directed toward the empirical validation of this technique as an effective treatment mode.

The assessment of EMG feedback as a treatment for the reduction of anxiety stress reactions has been the focus of several recent investigations. A single group study by Raskin, Johnson, and Rondetvedt (1973) indicated that EMG feedback is of limited value in the treatment of chronic generalized anxiety. Stoyva and Budzynski (1974), however, reported successful use of EMG feedback in the clinical treatment of "several dozen" pervasive anxiety patients. Several controlled studies comparing the effectiveness of EMG feedback and modified types of progressive relaxation training were in general agreement that EMG feedback was superior to progressive relaxation training with regard to speed of learning and depth of relaxation obtained (Coursey, 1975; Haynes, Moseley, & McGowan, 1975; Reinking & Kohl, 1975). These latter studies contained normal subjects who were not involved in a stress situation. It is clear that the comparative effectiveness of EMG feedback and progressive relaxation training in reducing anxiety under natural, stress-provoking circumstances has yet to be determined.

The purpose of this study was twofold—(a) to ascertain the effects of relaxation training on anxiety stress reactions in a dental setting and (b) to determine the comparative effectiveness of EMG feedback and progressive relaxation in relieving anxiety stress reactions of a relatively circumscribed, though reoccurring, nature. The following hypotheses were tested:

1. EMG feedback and progressive relaxation training will lead to significant decreases

in anxiety stress reactions as compared to self-relaxation control procedures.

2. EMG feedback relaxation training will produce significantly greater stress reduction than will progressive relaxation training.

Method

Subjects

A list of patients classified as prone to anxiety stress reactions in a dental setting was compiled by a dentist from his total active file of patients on the basis of the dentist's observations over time and also on patients' verbal reports to him. The patients were contacted by phone by the dentist to determine their interest in participating in a study of treatment techniques aimed at the reduction of stress reactions in dental situations. Those patients who were interested were scheduled for an initial interview that included a brief medical-dental history and a dental examination. Any patient who either was currently using drugs that might effect the results of the study or who was being seen regularly by other health service providers was excluded from the study. The subjects who were included required dental work of a simple restorative nature entailing at least two separate dental appointments. The final list included 21 subjects (17 females, 4 males). The disproportionate male/female ratio resulted from two factors: (a) Twice as many females ($n = 28$) as males ($n = 14$) were originally identified by the dentist as stress prone in a dental setting, and (b) the males who were contacted were more reluctant to participate in the study than were the females. Subjects ranged in age from 21 to 48 years, with a mean age of 35 years.

Apparatus

EMG measures were recorded with an Autogen 1500 feedback myograph using standard frontal placements 2 inches (5.08 cm) on either side of the center of the forehead and 1 inch (2.54 cm) above each eyebrow (Venables & Martin, 1967). A ground electrode was secured to the forehead midway between the other electrodes.

Connected to the Autogen unit were stereophonic headphones through which subjects in the EMG feedback group received auditory feedback of ongoing muscular tension. This feedback was presented in the form of clicks that were logarithmically proportional to the level of EMG activity being monitored. All meter readings were based on average integral microvolts.

Procedure and Measures

During the first phase of the initial dental appointment in which actual dental work occurred,

baseline frontalis EMG readings were taken. After a 3-min adaptation period while the patient was seated in the dental chair, the baseline EMG readings were recorded once every 10 sec for a 3-min period and were averaged to obtain a single score. After removal of the electrodes, each subject completed a set of self-report measures including the Dental Anxiety Scale (DAS; Corah, 1969) and the State-Trait Anxiety Inventory (STAI; Spielberger, Gorsuch, & Lushene, 1970). Upon completion of these measures, the scheduled dental treatment began. At the conclusion of the initial dental appointment, all subjects were scheduled for 10 training or control sessions to extend over a 4-week period. Both dental appointments and all training sessions were scheduled at approximately the same time of day, with a maximum deviation of 2 hours for any 1 subject. Subjects were then randomly assigned to one of three groups ($n=7$ each): EMG feedback training, progressive relaxation training, or self-relaxation control.

Subjects in the progressive relaxation group received 10 training sessions 10–40 minutes in length in the manner standardized by Bernstein and Borkovec (1973). The longer time periods were necessary for completion of training during the first three sessions, with session length decreasing as the training progressed. All training was completed while the subjects' eyes were closed. The progressive relaxation training was "live," rather than prerecorded on tape, as Paul and Trimble (1970) have shown the former method to be significantly more effective in reducing stress responses.

In the EMG feedback group, subjects also received 10 training sessions. Each session was 20 minutes long (Budzynski & Stoyva, 1969). EMG subjects were told that they would be hearing clicks through the headphones that would be proportional to their moment-to-moment muscular tension (i.e., the clicks would increase in speed as their tension level increased and would decrease in speed as they relaxed). EMG subjects were then instructed to close their eyes and to slow down the speed of the clicks.

As with subjects in the treatment groups, control subjects met with the experimenter for 10 sessions. Each session was 20 minutes in length. The control subjects were told, as were subjects in the other groups, that they were participating in a study designed to see whether practice in relaxation might help people feel more comfortable during future dental appointments. After being instructed to close their eyes, control subjects were asked to relax themselves as best they could. These subjects were not informed of the control aspect of their participation.

Treatment and control sessions were conducted in the physical therapy room of a physician's office adjacent to the office of the participating dentist. The room was well insulated from sound on all sides. During relaxation sessions all subjects reclined on a hospital bed with the experimenter seated in a nearby chair. In all cases, the second dental appointment was scheduled within 2 weeks after completion of the 10 relaxation sessions. EMG recordings of

muscle tension levels and self-report data were collected in an identical manner as that collected during the first dental appointment. The dentist who recorded EMG levels and collected self-report data was unaware of the experimental group to which each patient was assigned.

Routine dental checkup notices were mailed to all subjects approximately 1 year after their second experimental dental appointment. Those subjects who responded to this call for checkup appointments and who on examination required dental treatment other than routine cleaning were scheduled for a follow-up appointment. EMG levels and self-report data were collected in the same manner as in the first and second dental appointments.

Results

EMG Levels

Training sessions. The mean EMG levels in microvolts for all groups were determined for each of the 10 training or control sessions that occurred during the period between dental appointments. Figure 1 shows the EMG trends for each group across these 10 sessions. If it is assumed that learning to relax is accompanied by progressively lower EMG levels across sessions, significant linear trends for each group would be one indicator that learning had occurred. Separate tests for trends across the 10 training sessions for each group showed significant linear trends for the progressive relaxation, $F(1, 18) = 8.93, p < .01$, and the EMG feedback, $F(1, 18) = 6.31, p < .05$, groups but not for the control group (F

= .46). Further analysis of the data was accomplished through use of a 3×10 (Groups × Training Sessions) analysis of variance (ANOVA), with the results being presented in Table 1. Of particular interest is the Groups × Training Session interaction, which indicates significant differences in trends among groups. Although a significant difference among linear trends would be an expedient way of showing differential learning among groups, it can be seen from Table 1 that this linear trend difference was not significant. As a result, trends other than linear must be considered in order to account for the significant Groups × Training Sessions interaction. Therefore, although significant differences among linear trends were not shown, the progressive relaxation and EMG feed-

back groups did show significant linear decreases in EMG levels while the control group did not.

Dental appointments. The mean EMG level in microvolts for each group across dental appointments is presented in Table 2, as are the results of a 3×2 (Groups × Appointments) ANOVA. A significant decrease in EMG level across dental appointments was found. Even though the Groups × Appointments interaction was not significant, planned analysis of the data using an ANOVA for simple main effects showed that significant decreases in EMG levels from the first to the second dental appointment occurred in the EMG feedback ($p < .05$) and the progressive relaxation ($p < .05$) groups but not in the control group. Although EMG levels for both the

** $p < .001$.

EMG feedback and progressive relaxation groups were reduced significantly across dental appointments, these decreases were not significantly different from each other.

Dental Anxiety Scale

Table 3 consists of the mean score on the DAS for each group across appointments and the results of a 3×2 (Groups × Appointments) ANOVA. A significant decrease in DAS scores occurred between dental appointments, as demonstrated by the significant main effect. Further, a significant Groups × Dental Appointments interaction was also shown. A planned ANOVA for simple main effects accounted for the interaction effect by demonstrating that first, all groups evidenced a significant decrease in scores across appointments (for EMG feedback, $p < .001$; for progressive relaxation, $p < .001$; for controls, $p < .05$), and, second, the groups' scores, although not differing on the first dental appointment, did differ significantly on the second ($p < .05$). Individual comparisons indicated that even though there was no significant difference between the EMG feedback and progressive relaxation scores at the second dental appointment, the mean of these scores differed significantly ($p < .05$) from that of the control group. A t test on the difference scores between appointments for the EMG feedback and progressive relaxation groups was not significant. Thus, DAS scores for all groups showed significant reductions; however, the reductions shown by the EMG

feedback and progressive relaxation groups, while not differing significantly from each other, were significantly lower than those in the control group.

STAI-State. In Table 4 the mean STAI A-State scores for each group and the results obtained from a 3×2 (Groups × Appointments) ANOVA are presented. Main effects for groups ($p < .05$) and appointments ($p < .001$) and the interaction effect ($p < .001$) were significant. A planned ANOVA for simple main effects revealed significance for groups at both levels of appointments and for appointments at all levels of groups. Individual comparisons showed that at the first appointment, the score of the progressive relaxation group was significantly lower than that of the EMG biofeedback group ($p < .05$); however, the score of neither the progressive relaxation group nor the EMG biofeedback group differed significantly from that of the control group. At the second dental appointment, the score of the EMG biofeedback group did not differ significantly from that of the progressive relaxation group, although the scores of both the EMG biofeedback ($p < .01$) and the progressive relaxation groups ($p < .01$) differed significantly from that of the control group. A t test of difference scores between appointments for the EMG biofeedback and progressive relaxation groups was not significant. Thus, all groups showed significant decreases in A-State scores; however, even though the reductions shown by the EMG biofeedback and progressive relaxation groups did not differ significantly from each

other, they were both significantly greater than the decreases shown by the control group.

Trait Anxiety. Table 5 includes mean Trait Anxiety scores for all groups across dental appointments and the results of a 3×2 (Groups × Appointments) ANOVA. A significant reduction was shown between scores on the first and second dental appointments. However, the Groups × Appointments interaction was not significant. Even though the subjects reduced their trait anxiety from the first to the second dental appointments, there was no differentiation among the three groups in the trait anxiety reduction effect.

Discussion

Both the training session data and the pre-post appointment data lend support to the

first hypothesis, which contends that EMG feedback and progressive relaxation training will lead to significant reductions in anxiety stress reactions as compared to self-relaxation control procedures. The second hypothesis, which holds that EMG feedback relaxation training will produce significantly greater anxiety stress reduction than progressive relaxation training, was not confirmed. Both treatment groups were equally effective in reducing transitory, situational anxiety such as that found in the dental setting.

A review of the data suggests that patients having recurrent anxiety stress reactions in dental settings may obtain a significant degree of relief from relaxation training with either EMG feedback or progressive relaxation techniques. The EMG levels of both the feedback and the progressive relaxation

groups showed significant decreasing linear trends across training sessions suggestive of learning. No such trend, however, was observed in the control group. Also, from the first to the second dental appointments, the feedback and the progressive relaxation groups showed significant decreases in scores on three of four dependent measures (EMG, DAS, A-State). Even though significant decreases were also shown by the control group on the latter two measures, these decreases were significantly less than those shown by the EMG feedback and progressive relaxation groups. No indication of a clear-cut superiority of one type of relaxation training over the other was shown on the EMG, DAS, or A-State measures as pertaining to situational anxiety. Rather, on the basis of this evidence, it would seem that patients in both the EMG feedback and progressive relaxation groups were more comfortable, physiologically and psychologically, when exposed to the immediate threat of dental stimuli after receiving relaxation training.

The consistency of findings for both treatment groups provides the suggestion of the mechanism for the reduction effect of the anxiety of the treatment groups. The learned reduction in EMG levels across sessions, shown by the decreasing linear trends, transferred to the posttreatment dental appointment. In addition to the reduced EMG levels that the patients exhibited in the dental chair immediately prior to the dental work, they reported less dental anxiety and state anxiety at that time. Apparently, the learned reduction in muscular tension that was a result of either the EMG feedback or the progressive relaxation procedures produced the reductions in both physiological and self-report measures of anxiety.

An important point to note is that the research under discussion here is a clinical treatment study. This represents a major difference between it and other studies that have investigated the comparative effects of relaxation techniques, notably the Coursey (1975) study and the Reinking and Kohl (1975) study, both of which contained normal subjects. As mentioned earlier, the subjects involved in the current study were tested under natural conditions, which to them were

highly stressful. Beyond the observations of the dentist who identified the dental-anxious subjects, representing less than 1% (original subject pool $N = 42$) of an available patient population ($N > 5,000$), other factors pointed to a high discomfort level among the subjects selected. Indicative of this discomfort were pretraining DAS scores and A-State scores, which ranked at about the 90th percentile when compared to scores found in normal populations (Corah, 1969; Spielberger et al., 1970). Further, the pretraining muscular tension levels of the subjects were approximately 32% higher than the pretraining levels of the normal subjects in the Coursey (1975) study and 23% higher than those in the Reinking and Kohl (1975) study. (For the purpose of comparison, the peak-to-peak microvolt readings reported in the latter two studies were divided by the constant 3 in order to approximate the average integral microvolt readings used here.)

In conclusion, direct clinical implications that lead from the results of this study point to EMG feedback relaxation training and live, therapist-directed progressive relaxation training as effective treatments for relatively short-lived but recurrent bouts of anxiety that are bound to a particular stimulus event.

Hemispheric Asymmetry and Jewish Intelligence Test Patterns

Colin Martindale
University of Maine

On the basis of intelligence test performance, Dershowitz and Frankel have hypothesized that Jewish subjects are less psychologically differentiated (more field dependent) than Protestant and Catholic subjects. It is argued that differential intelligence test patterns are better explained in terms of differential emphasis on abilities mediated by the left and right cerebral hemispheres. The hypothesis is advanced that Jewish subjects exhibit a tendency toward left-hemisphere dominance in comparison to Protestant and Catholic subjects. Evidence for, and implications of, the hypothesis are discussed.

Dershowitz and Frankel (1975) have recently summarized the results of a number of studies showing that Jewish subjects tend to be characterized by relatively low scores on some of the performance subtests of the Wechsler Intelligence Scale for Children (WISC) and of the Wechsler Adult Intelligence Scale. Scores on Picture Completion, Picture Arrangement, Block Design, and Object Assembly are low in relation to scores on the verbal subtests of Comprehension, Information, Arithmetic, and Similarities. Studies are cited as showing a similar but less extreme pattern in Protestant children and an even less extreme pattern in Catholic (Irish and Italian) children. Dershowitz and Frankel related these patterns to Witkin's (1967) concept of psychological differentiation. According to their hypothesis, Jewish subjects are less psychologically differentiated than Protestant or Catholic subjects.

Even though low levels of psychological differentiation have been shown to be related to poor performance on three of the subtests on which Jewish subjects exhibit relative deficits, Dershowitz and Frankel (1975) themselves admit that they are unable to account for the poor Picture Arrangement scores of Jewish subjects with this explanation. Further, they cite only one unpublished study (Litman,

Note 1)—in which a version of the Embedded Figures Test was used—that would directly support the differentiation hypothesis. Two published studies (Dershowitz, 1971; Wendt & Burwell, 1964) reported failures to find significant differences between Jewish and non-Jewish children on Embedded Figures Test performance, although differences were in the expected direction.

Dershowitz and Frankel's (1975) findings are more parsimoniously explained by the hypothesis that Jewish subjects show a relative superiority on tasks that are dependent on the left cerebral hemisphere and a relative deficit on tasks that are dependent on the right cerebral hemisphere, whereas Protestants show a similar but less extreme pattern and Catholics are relatively balanced in their performance. Recent research using a number of strategies—such as split visual-field stimulation, dichotic listening, and recording electroencephalogram during task performance—has led to the hypothesis that the left hemisphere is specialized for linguistic, analytical, and sequential tasks, whereas the right hemisphere is specialized for tasks requiring holistic, spatial abilities. To my knowledge, no one has used these strategies to test for differential performance as a function of subjects' religious backgrounds. However, a number of studies of the intellectual effects of unilateral brain damage have been conducted. (See Goldstein, 1974, for a review.) Although there are a few exceptions, almost all have

shown that left-hemisphere damage leads to deficits on the verbal subtests of the Wechsler-Bellevue and the Wechsler Adult Intelligence Scale, whereas right-hemisphere damage leads to deficits on the Performance subscales (including Picture Arrangement) of these tests.

Dershowitz and Frankel (1975) used the slope of the regression line relating scaled score to rank of subtest difficulty (across all of their groups) as an index of degree of performance subtest deficit. The order of subtest performance from worst to best was as follows: Object Assembly, Picture Completion, Block Design, Picture Arrangement, Similarities, Arithmetic, Information, Comprehension. Thus, the steeper the slope, the greater the performance subtest deficit. Pooling the means presented in Dershowitz and Frankel's Table 1 (p. 127), I obtained slopes of .55 for 546 Jewish subjects, .31 for 30 Protestant subjects, and .25 for 94 presumably Catholic (Irish and Italian) subjects. (All of the slopes are positive because the tests were ordered on the basis of the performance of all groups in the first place.)

Several studies of unilateral brain damage include full tables giving mean subtest scaled scores of left- and right-hemisphere-damaged subjects on the Wechsler Adult Intelligence Scale and on the Wechsler-Bellevue Scale. If the Dershowitz and Frankel (1975) technique is applied to these means, slopes of .54 for 23 right-hemisphere-damaged subjects and of .06 for 21 left-hemisphere-damaged subjects are obtained for the means reported by Simpson and Vega (1971). Slopes of .35 for 31 right-hemisphere-damaged subjects and $-.33$ for 29 left-hemisphere-damaged subjects are obtained using the figures reported by Dennerll (1964). Unfortunately, in neither of these studies is the religious background of the subjects specified. The slope of .55 for Jewish subjects is essentially the same as one of the slopes obtained for right-hemisphere-damaged subjects and is somewhat higher than the other slope for right-hemisphere-damaged subjects. This is, of course, consistent with the hypothesis of a relative left-hemisphere dominance in Jewish subjects.

The notion that Jewish subjects exhibit a pattern of relative left-hemisphere dominance is not necessarily inconsistent with the hy-

pothesis that they tend to be field dependent. In fact, on the basis of a review of the effects of right-hemisphere damage, Pizzamiglio and Carli (1974) have hypothesized that right-hemisphere damage leads to field-dependent behavior. The implication of the hemispheric dominance hypothesis would be that the field-dependent test behavior of Jewish subjects does not arise from a lack of psychological differentiation on the level of personality but is, rather, an artifact of a more basic pattern of cognitive abilities. The hemispheric dominance hypothesis would seem, further, to be the more general and preferable one in that it can subsume the findings explained by the psychological differentiation hypothesis as well as others not explained by the latter hypothesis. Finally, the hemispheric dominance hypothesis predicts relative strengths as well as weaknesses for each of the religious groups.

In regard to intellectual test performance, the perceptual differentiation hypothesis cannot account for the poor performance of Jewish subjects on the WISC Picture Arrangement subtest, but the hemispheric dominance hypothesis can: Right-hemispheric damage depresses Picture Arrangement scores more than does left-hemispheric damage (McFie, 1960). It is not well established that Jewish subjects exhibit poor performance on the Embedded Figures Test. Only one of three studies obtained significant results in this direction. This may be because this test is dependent on both linguistic (left-hemisphere) and spatial (right-hemisphere) abilities: Aphasia causes decrements on this task (Teuber & Weinstein, 1956), but there is evidence that in patients without aphasia, right-hemisphere lesions cause greater decrements than do left-hemisphere ones (Russo & Vignolo, 1967). One study suggests that Jewish subjects perform more poorly than non-Jewish subjects on the Body Adjustment Test (Dershowitz, 1971). This is, of course, consistent with the psychological differentiation hypothesis. I know of no studies of the effects of lateralized lesions on this task, but the mediation of a wide variety of spatial orientation behaviors by the right hemisphere (cf. Luria, 1973) suggests that this finding should cause no problems for the hemispheric dominance hypothesis. Finally, the finding that

the figure drawings of Jewish children suggest field dependence (Dershowitz, 1971) is paralleled by the finding that right-hemisphere lesions produce a similar effect (Pizzamiglio, Note 2).

The hemispheric dominance hypothesis leads to a number of predictions that cannot be derived from the psychological differentiation hypothesis. On the basis of findings with lateralized lesions, we would expect Jewish subjects to perform worse than non-Jewish subjects on tasks such as three-dimensional size discrimination (cf. Weinstein, 1964), identification of faces (cf. Hécaen & Angelergues, 1963), and tactual form identification (cf. Pizzamiglio & Carli, 1974) but better than non-Jewish subjects on tasks involving verbal fluency and abstraction (cf. Luria, 1973).

The hypothesis that Jews, Protestants, and Catholics differ in degree of emphasis on processes dependent on one or the other hemisphere is consistent with a number of cultural and religious practices. For example, Jewish and Protestant religious rituals emphasize linguistic stimuli and deemphasize complex spatial stimuli such as images, stained glass windows, and elaborate architectural detail. Just the opposite is true of Catholic ritual. In old Hebrew, only consonants were written. Interestingly, the superiority of the left hemisphere in recognition of linguistic material is strongest for consonants (Studdert-Kennedy & Shankweiler, 1970). The right-to-left writing of Hebrew is also consistent with the finding that right-hemisphere weakness leads to perceptual left-side "neglect" (Luria, 1973). These and other consistencies do not, of course, prove the existence of the hypothesized hemispheric asymmetry nor do they tell us whether it causes the cultural differences or vice versa. (It seems likely that cultural differences bring about the differential emphasis on one or the other hemisphere, since Dershowitz and Frankel, 1975, presented evidence that the degree of Jewish weakness on spatial tasks decreases with acculturation as opposed to "traditional" subjects.) If the three groups do in fact tend to process and code information in the differential ways suggested, this would shed some potentially helpful light on the reasons for their historical conflicts. On a more prosaic level, it seems

clear that religion and ethnic background may be rather potent nuisance variables in use of intellectual test patterns in connection with diagnosis of left- and right-hemisphere brain damage.

Therapeutic Relationship in Behavior Therapy: An Empirical Analysis

Julian D. Ford
University of Delaware

The determinants and predictive utility of the client's perception of the therapeutic relationship (CPTR) were investigated in the context of a behavior therapy clinical research project evaluating three approaches to assertion training. Individual differences in therapists were a significant determinant of CPTR. Neither therapy type nor therapy session accounted for much variance in CPTR, although CPTR ratings by individual clients varied from session to session. CPTR was an effective predictor of dropping out when measured early in therapy, and of immediate posttherapy client gains when measured in a mid-to late therapy session, but not of long-term maintenance of client improvements. Patterns of therapist behavior that were predictive of CPTR at three time points in therapy are delineated. It is speculated that CPTR is largely a function of the degree to which the client's expectation of the therapist and the consequences of therapy are being fulfilled. It is concluded that CPTR has significant predictive value, and perhaps also causal impact, in behavior therapy.

The therapeutic relationship between client and therapist is widely acknowledged as a central factor in producing positive outcomes in psychotherapy and counseling (cf.

This study is based on a dissertation submitted in partial fulfillment of the requirements of the PhD degree at the State University of New York at Stony Brook. The guidance and encouragement of Leonard Krasner, Committee Chairman, and Marvin R. Goldfried, David Pomeranz, David Cross, and Aaron Carton, the other committee members, is gratefully acknowledged. Philip C. Kendall contributed very valuable comments on an earlier draft of the article. Special thanks are due to the persons who served as therapists in the study: Virginia Roswell, Judith Graeff, Lynn Turlette, Cheryl Fishbein, James Waters, Joan Broderick, Charles Harris, Gary Swan, Steve Friedman, Arthur Nezu, Arthur Stone, Jerry Friedman, and Leonidas Castro; and to Marvin Goldfried for enabling the study to be conducted in his clinical research project.

The study was conducted in conjunction with an assertion training outcome study reported by Linehan, Goldfried, and Goldfried (Note 1). Results concerning the comparative efficacy of the three therapy interventions are detailed in that report.

Requests for reprints should be sent to Julian D. Ford, Department of Psychology, Wolf Hall, University of Delaware, Newark, Delaware 19711.

Howard & Orlinsky, 1972; Kiesler, 1973; Marsden, 1971; Meltzoff & Kornreich, 1970; Mitchell, Bozarth, & Krauft, 1977). Within the behavior therapy framework, increasingly greater attention has been paid to the therapeutic relationship in recent years (cf. Wilson & Evans, 1976). However, very little empirical research has been reported to directly evaluate the impact of variations in the therapeutic relationship on the outcome of behavior therapies. This study represents an initial attempt to address that issue.

Although the therapeutic relationship can be assessed from several vantage points (i.e., the client, the therapist, experienced clinician observers, nonexpert observers), and in terms of either specific client-therapist behavioral interactions or the global experiencing of the client and therapist, only one approach to the measurement of the therapeutic relationship has been well validated as a predictor of therapy outcome: the client's perception of the therapeutic relationship (CPTR) (cf. Gurman, 1977). Despite optimistic early reviews (Truax & Mitchell, 1971), there is no consistent evidence that ratings by nonexpert observers of the therapeutic relationship are predictive of outcome in therapy (cf. Mit-

chell et al., 1977). All other approaches to the measurement of therapy processes have received little, if any, empirical evaluation as predictors of therapy outcome, with very few promising results (e.g., Dietzel & Abeles, 1975; Mintz & Luborsky, 1971; Rice, 1965).

Although CPTR has been found to be an excellent predictor of therapeutic outcome in client-centered, psychoanalytic, vocational guidance, and "personal" therapy and counseling (Gurman, 1977), this has been done only three times in a behavior therapy context, and these studies have had important methodological limitations. In an analogue desensitization study conducted with mildly phobic volunteer subjects, Carmichael (cited in Gurman, 1977) found CPTR to be inversely predictive of decreases in avoidance behavior and not predictive of changes in subjective fear. Ryan and Gizynski (1971) found that retrospective CPTR reports were correlated with therapists' global ratings of client improvement after receiving unspecified types of therapy by self-identified behavior therapists. Sloane, Staples, Cristol, Yorkston, and Whipple (1975) also showed that retrospective CPTR reports were predictive of outcome in unspecified types of therapy administered by self-identified behavior therapists, using global ratings by clients, therapists, and expert judges as their outcome criteria.

The designs and results of these studies leave a major question unanswered. Is CPTR predictive of changes in therapy clients' *specific behaviors and self-perceptions* that are caused by participation in a *clearly described naturalistic* program of behavior therapy? Although the value of CPTR as a predictor of global improvement in behavior therapy has been demonstrated, it is unclear whether it is predictive of the more behaviorally specific criteria that are essential in behavior therapy. And, the therapy types used in these studies were either too incompletely described to permit replication or too artificial to be generalized to actual clinical practice.

Furthermore, these studies all measured CPTR retrospectively, so it is not possible to infer whether it would, if assessed prior

to the termination of therapy, serve as a clinically viable predictor of therapy outcome. Nor can we say whether CPTR remains constant across the course of therapy or whether it is differentially effective as a predictor at different time points.

Finally, there has been very little research in any therapy approach, and none in a behavior therapy context, that delineates the determinants of CPTR (cf. Gurman, 1977). If CPTR is important, how does it come about? Research on client and therapist personal and professional characteristics (e.g., age, psychological status, expertise, mood, dogmatism) as predictors of CPTR is sparse and inconclusive at present (see Gurman, 1977). When observers' ratings of therapist in-session behavior are tested as predictors, many verbal, vocal, kinesic, and proxemic behaviors have been examined, but very few have emerged even in one study (let alone in replications) as viable predictors of CPTR (e.g., therapist interruptions; vocal expression of concern and involvement; eye contact, forward trunk lean; see Gurman, 1977). Clearly, very little is known about the determinants of CPTR in any therapy context.

One study that has examined this issue using a factorial analysis of variance design demonstrated that the emergent events in each therapy session were the major causal factor underlying CPTR (Howard, Orlinsky, & Perlstein, 1976). But what are those events (e.g., What is it that the therapist is saying or doing that facilitates positive CPTR?), and does this hold true in a behavior therapy context as well? These issues are examined in this study.

Method

Clients

The clients were 39 volunteers from scattered suburban communities in the vicinity of a major east coast university, who responded to announcements in the media of a time-limited therapy program for assertion training. Persons responding to the announcements were sent a brief description of the program, which included the following information:

We hope to achieve two goals: first of all, to assist people like yourself who have difficulty

acting assertively or who experience anxiety or nervousness in situations where they want to act assertively. At the same time, we hope to obtain valuable information regarding the types of treatment methods that are most effective for different individuals. All of the treatment procedures we will be using in the assertion program have been shown to be effective for some individuals.

The therapists will be PhD candidates in clinical psychology trained and supervised by Dr. Goldfried. . . . We are unable to accept anyone into the program who is currently being seen in psychotherapy. . . . The treatment sessions will consist of weekly *individual* sessions carried out over a 2-month period, with each session lasting approximately 1 hour. . . . Because the program is being funded by the National Institute of Mental Health, there will be no charge to you. . . . We want to again emphasize that your questionnaire responses and what transpires during the actual assertive training sessions will be kept strictly confidential.

Persons applying to the program were screened (a) to eliminate client sex as a factor, and since the vast majority of applicants were women, only females were accepted as clients; (b) university students were not accepted in order to obtain a representative sample of community adults; (c) persons concurrently undergoing psychotherapy were not accepted, nor were persons who showed evidence of severe marital problems or thought disorder; and (d) only applicants who scored below zero on the Rathus (1973) Assertiveness Schedule and above three on an assertion screening inventory designed especially for this study (Personal Reaction Inventory, Form D) were accepted as participants. All persons who volunteered were screened in an interview conducted by an experienced clinical psychologist. Applicants who met the screening criteria were accepted as clients until all therapists participating in the study were matched with three clients; thereafter, applicants were referred to other clinics and assertion training programs in the area with the explanation that the program could no longer accept further applications.

All clients reported in the screening interview that problems with assertiveness had generalized debilitating effects on their lives (e.g., self-confidence, marriages, vocations). The average pretherapy score on the Rathus (1973) Assertiveness Schedule was -46.3 , markedly below the mean scores reported by Rathus for a nonclinical college population (i.e., $.3$ and 1.6). Thus although it must be emphasized that these clients were solicited for assertion training therapy rather than self-referred for psychotherapy, there is evidence that the problems in living that confronted them were clinically serious.

The clients' average age was 36.5 years (range = 22-60), and they had an average education level of

2 years in college (range = 10-17 years of education). Seventy percent were married. Ten were unemployed outside the home, 8 had part-time jobs, and 12 held full-time jobs.

Therapists

The 13 therapists were advanced graduate students in a clinical psychology training program (M age = 28.6). Eight were male, and 5 were female. All but 1 were inexperienced (Mdn = seven prior cases).

Therapy Types

Clients were matched using within-group procedures on the basis of age and scores on all pretest measures (see Table 1) and were then randomly assigned to one of three therapy types (Linehan, Goldfried, & Goldfried, Note 1): interactive, in which therapists focused on providing nondirective support to the client; instigation, in which homework assignment to engage in assertive behaviors was provided as a supplement to therapist support; and, rational restructuring, in which clients were trained to restructure their cognitive self-statements (cf. Ellis, 1970) through modeling and behavior rehearsal, in addition to receiving behavioral instigation and emotional support. All clients received an explanation of why people are unassertive and how one can become more assertive that was congruent with their therapy types in the initial session.

Each therapist conducted each type of therapy with an individual client over eight 1-hour weekly sessions. Two therapists had one client drop out, one therapist had two clients drop out, and one therapist had one client drop out and two clients who failed to provide pretest data. Thus, there were 32 clients who completed the entire therapy process.¹

Measurement of the Perceived Therapeutic Relationships

The Relationship Inventory Form G (RI-G), as developed by Gorman (1973), was used to assess the client's perception of the therapeutic relationship at three points in the therapy process (i.e., immediately after the third, sixth, and final therapy sessions). The RI-G is a 30-item true-false written questionnaire that was derived from similar previous instruments. Ten-item subscales can be scored for empathy, warmth, and genuineness, but reli-

¹One of the clients who completed therapy was not included in the data analyses because her therapist had both of his other clients drop out, and was thus not representative of the other therapists (none of whom had more than one client drop out).

ability has been assessed only for the entire scale; split-half Spearman-Brown reliability was reported to be .86 by Gurman (1973).

Measurement of Therapist Behaviors

Twelve 3-minute samples were taken from audiotapes of each of the 31 complete therapy cases.

(Friedman, 1971)

Therapy Sessions 1, 3, 6, and 8 were sampled, with one 3-minute sample taken from the middle of the first (i.e., early), second (i.e., middle), and final (i.e., late) third of each session. Eight trained research assistants rated the therapist's behavior from the audiotaped time samples and written transcripts. Each rater rated an equal number of tape segments from all therapists, clients, therapy types, therapy sessions, and in-session time periods. Raters were assigned to teams of two or three, and each team rated one third of the behavior categories so as to minimize rater overload.

The therapist behavior code that was used for ratings consists of 48 behavior categories, each operationally defined in detail and derived from existing therapy process measurement instruments (see Table 2). Each category was rated once every 20 sec, or nine times in each 3-min sample. The data were condensed by means of arithmetic averaging to provide one score for each 3-min time sample.

Reliability was assessed by having each rater re-rate 48 (for the three-person teams) or 72 (for the two-person team) 3-minute segments already rated by each other rater in his/her team. These segments were equally distributed across therapists, clients, therapy types, therapy sessions, and in-session time periods. Reliability was assessed by means of Pearson product-moment correlations for variables that were scored as frequency counts or ordinal ratings. Reliability coefficients ranged from .70 to .99, with a median of .82. For the variables that were scored simply as occurrence or nonoccurrence, Cohen's (1960) Kappa was used as a reliability estimate, since it accounts for chance agreements when the more typically used percentage agreement score does not. When Kappa was calculated for interrater agreement on both occurrence and nonoccurrence, reliability ranged from .77 to 1.00, with an average of .87. With the much more conservative test of agreements on occurrences only, the levels were .40 or higher (i.e., well above chance), with only one exception (i.e., topic change, .28), and with an average of .73.

Measurement of Therapeutic Outcome

Thirty separate variables were used to assess therapy outcome (see Table 1). Seventeen variables were derived from written questionnaires completed by clients before, immediately after, and 2 months after therapy. These self-report measures assess a variety of components of assertion, including self-perception of assertiveness, anxiety, hostility, depression, and masculinity-femininity as general traits and as behavioral reactions to specified situations. All of the measures have been well researched and have been extensively used to evaluate outcome in prior assertion training research (cf. Rich & Schroeder, 1976), although none have clearly demonstrated external validity.

Eleven variables were taken from the client's

subjective emotional reactions to, and observer ratings of client behavior in, six role-playing simulations requiring assertion and were measured only at pretest and posttest (Table 1).

Finally, two variables were assessed at posttest only: observer ratings of 2 categories of client behavior in an analogue "stress test."

Trained research assistants served as observers for the behavioral outcome measures. Interrater agreement levels were calculated by product-moment correlations between two observers for each variable. Reliability levels were as follows: role-playing assertiveness content ($M = .85$, range = .84-.87); role-playing loudness/affect ($M = .92$, range = .78-.97); role-playing disfluency ($M = .88$, range = .83-.92); and stress test assertiveness content ($M = .84$, range = .69-.96).

Pretest, posttest, and follow-up scores were converted to outcome scores through the use of residual gain scores (Manning & DuBois, 1962), which were used rather than raw difference scores because of their greater reliability and their control for regression effects due to pre-post or pre-follow-up correlation.²

Results

Variation in the Perceived Therapeutic Relationship

Three two-way analyses of variance (ANOVAS) were conducted, with RI-G scores as the dependent measure, to determine the proportions of variance in CPTR accounted for by differences among therapists, therapy types, and therapy sessions: (a) Therapists \times Therapy Types (pooling over therapy sessions); (b) Therapists \times Therapy Sessions (pooling over therapy types); and (c) Therapy Types \times Therapy Sessions (pooling over therapists). A single three-way ANOVA was not used, since it would have involved one data score per cell, thus confounding the Therapist \times Therapy Type and Therapist \times Therapy Type \times Therapy Sessions interaction terms with the error term. Variance proportions were calculated based on expected mean square formulas (Winer, 1971) and the assumption that therapist is a random between-subjects factor, therapy type is a fixed between-subjects factor, and therapy session is a fixed within-subjects (repeated measures) factor (cf. Endler & Hunt, 1968).

² Those correlations were noteworthy in this study, with 75% falling in the .32-.78 range ($p < .05$) and more than half greater than .52.

Table 3
Determinants of Variance in the Perceived Therapeutic Relationship

Factor	A × B	A × C	B × C	Overall
Therapist (A)	.20	.43	—	.315
Therapist type (B)	.02	—	.01	.015
Therapy session (C)	—	.08	.07	.075
A × B	.18	—	—	.180
A × C	—	.05	—	.050
B × C	—	—	.07	.070
Residual	.60	.44	.85	.295

Note. Determinants are expressed as proportions, varying between .00 and 1.00. Overall variance proportions for therapist, therapy type, and therapy session were determined by numerically averaging the two values for each. The overall variance proportion for the residual term was calculated by subtracting the overall variance proportions of all other factors from 1.00. The residual term includes the variance due to the highest order interaction term and error.

The results (Table 3) demonstrate that differences between the individual therapists had a significant effect on CPTR, the interaction of therapists and therapy types had a moderate impact, and all other factors exerted only a minimal influence. Only one factor achieved a significant *F* in any ANOVA (i.e., Therapist, in the Therapist × Therapy Session ANOVA).

A *t* test was conducted to examine whether the therapist's gender was a significant determinant of CPTR ratings. The results showed that male and female therapists did not receive significantly different CPTR ratings, $t(91) = .1$, and this is reflected in the mean ratings for males (27.1) and females (26.8).

Perceived Therapeutic Relationship as a Predictor of Outcome

Correlation coefficients were calculated between RI-G scores and the scores for each outcome measure separately for Sessions 3, 6, and 8. The results (Table 4) show that RI-G scores were not consistently predictive of therapy outcome at Session 3, with only 4 of 47 correlations at or near significant. However, Session 6 RI-G scores were consistently predictive of posttest outcome, with 18 of 30 correlations at or near (i.e., $p = .06$) significant, all in the expected direction. Session 6 RI-G scores were not consistently predictive of follow-up outcome, with only 4 of 17 correlations significant. Session 8

RI-G scores were not consistently predictive of outcome, with only 4 of 47 correlations significant.

CPTR was assessed as a predictor of premature termination by comparing the Session 3 RI-G scores of the five dropouts with those of the 31 full-term clients. Mean RI-G levels for the two groups were 14.6 and 27.3, respectively. A *t* test showed that the clients who completed therapy gave significantly higher RI-G ratings for Session 3 than did the dropouts, $t(34) = 8.1$, $p < .001$. Few false positives or negatives were found, as well: RI-G scores for three dropouts were much lower than those for any full-term client; the fourth dropout's RI-G score was equal to the lowest RI-G score for any full-term client; and, the fifth dropout's RI-G score was lower than all but two of the full-term clients' RI-Gs.

Therapist Behavior as a Predictor of CPTR

The therapist behavior categories were grouped into 14 composite behavioral "styles" on an a priori basis to permit for relatively reliable stepwise multiple regression analyses with the small sample size (see Table 5). The multiple regression analyses were conducted separately for each of the three therapy sessions for which RI-G ratings were obtained.

Results from the nine multiple regression analyses are presented in Table 6. Overall, therapist behaviors did not account for the

major part of the variance in RI-G scores, generally explaining between 15% and 30% of the variance in CPTR. However, in the early phase of both Sessions 6 and 8, therapist behavior accounted for substantial proportions of RI-G variance (i.e., 48% and 53%).

Although there was much variation from session to session, and time period to time period, certain styles were consistently positively related to favorable CPTR (i.e., focus on behavior or cognitions; nonverbal style; cognitive restructuring), whereas one was often inversely related to RI-G scores (i.e., significant others).

Discussion

The fact that the client's perception of the therapeutic relationship seems to be a potent factor in behavior therapy is consistent not only with prior research (Gurman, 1977) but also with two important current developments in behavior therapy. First, there is growing recognition that the (ostensibly) same technique (e.g., desensitization), when applied by different therapists or at different time points or in different settings or with different clients, may be implemented quite differently and with different outcomes. Behavior therapists have

developed precautions (e.g., Paul, 1969) against the "therapist uniformity myth" (Kiesler, 1966) for many years now. However, it is recognized that it is not sufficient to only control for "nonspecific" effects: We must attempt to determine what it is in the moment-to-moment behaviors of therapists that affects clients and how these specific behaviors interact with behavior change techniques—and differences in therapists, clients, settings, and target objectives—to produce more or less successful outcomes (cf. Wilson & Evans, 1976). Only then will systematic training and research replication be possible.

Second, the significance of the client's perceptions and cognitions (i.e., attributions, self-statements, expectations) in behavior change and maintenance has been convincingly established by the cognitive therapists (e.g., Beck, 1970; Ellis, 1970) and cognitive behavior therapists (e.g., Lick & Bootzin, 1975; Mahoney, 1974). Self-perception,

self-reinforcement functions, expectancy of gain, cognitive distortions, and cognitive coping strategies have been extensively considered in recent behavior therapy theory and research. Now, CPTR can be added as a researchable cognitive factor of potential practical importance.

Variance in CPTR

Individual differences among therapists emerged as the primary determinant of CPTR, consistent with previous research on therapeutic process in contexts other than behavior therapy (cf. Meltzoff & Kornreich, 1970). Further research will be needed to pinpoint just what it is that differentiates therapists who evoke more or less CPTR (e.g., mood states; cognitive styles). A *t* test conducted to explore the possibility of sex differences was nonsignificant, indicating that therapist sex was not a factor in this study. It should also be noted that replication with

Note. There were no predictors for Session 3, Time 1 and Session 6, Time 3.

more experienced therapists will be necessary to rule out the possibility that individual differences among therapists are only factors with relatively inexperienced therapists.

Surprisingly, therapy type had virtually no effect on CPTR. Apparently, the same therapist can establish rapport as effectively when applying systematic cognitive and behavioral interventions as when focusing exclusively on offering nondirective emotional support. This result is consistent with prior research showing that behavior therapists are equally able to evoke positive CPTR as compared to other therapists of other orientations (e.g., Fischer, Paveza, Kickert, Hubbard, & Grayston, 1975; Sloane et al., 1975).

The particular therapy session also accounted for relatively little of the variance in CPTR. However, in contrast to previous research, which showed that CPTR measures have excellent temporal stability (Gurman, 1977), the correlations between RI-G

scores at the three different time points were .05 (Session 3 to Session 6), .05 (Session 3 to Session 8), and -.56 (Session 6 to Session 8). The data suggest that CPTR should be measured at several time periods across the course of therapy when used as either a research or clinical tool.

Because only one *F* ratio achieved significance in the three ANOVAs, and due to the relatively small sample sizes, replication with larger *N*s seems advisable to confirm the finding that only therapist factors contributed substantially to variance in CPTR, and to rule out the possibility of chance findings.

CPTR as a Predictor of Outcome

CPTR was shown to have value as a predictor of two key therapeutic outcomes: staying in therapy and making changes in behavior and self-perception. Although this is consistent with previous research (e.g., Ryan

& Gizynski, 1971; Sloane et al., 1975), replication is certainly needed with other behavior therapies, more experienced therapists, clinic-referred rather than volunteer clients, longer term and open-ended therapies, and in a naturalistic rather than research context before this conclusion can be generalized beyond the present study's context. However, the results have good external validity for several significant settings, populations, and therapy types, including novice therapists-in-training, brief time-limited therapies (Watzlawick, Weakland, & Fisch, 1974), therapeutic and educational interventions in which assertion training is the primary vehicle and target (Rich & Schroeder, 1976), and most behavior therapy outcome research projects (O'Leary & Wilson, 1975).

CPTR was never an effective predictor of long-term maintenance of client improvements as measured at the 2-month follow-up. This suggests that CPTR facilitates and/or is predictive of short-term therapeutic change but that long-term behavioral maintenance requires special therapeutic intervention (e.g., training in self-management skills; restructuring the client's natural environment). This is consistent with a major principle of behavior therapy: Behavioral generalization and maintenance must be programmed rather than lamented (cf. Baer, Wolf, & Risley, 1968). It also reconfirms the notion that therapist facilitativeness is a necessary but *not* sufficient ingredient in effective counseling and psychotherapy.

Therapist Behavior as a Predictor of CPTR

Given the importance of positive CPTR, the critical question remains as to what a therapist can do to establish rapport with each client. (i.e., What is the RI-G really measuring?) In Session 3, there were no effective predictors from the first in-session time period, but in the middle part of the session a focus on behavior or a warm, relaxed, and energetic nonverbal style, plus a focus on the client and not on her significant others, was optimal for CPTR. In the final time period, a stress on a collegial client-therapist relationship (i.e., "We" statements) plus either encouragement to take action or

a positive nonverbal style were associated with higher RI-G scores. Thus, it seems that CPTR is maximized in this early therapy session when the therapist communicates verbal and/or nonverbal encouragement, involvement, concern, and respect for the client. The behavioral correlates of CPTR in this session closely parallel those identified by previous research (Gurman, 1977). This is not surprising, since much of the previous research was done using behavior samples from sessions early in therapy. This type of verbal and nonverbal approach is thought to be essential to creating "rapport" in early sessions by behavior therapists (e.g., Wilson & Evans, 1976) as well as by therapists of other theoretical orientations.

In the early phase of Session 6, a focus on the client rather than on her significant others, and in particular on her cognitive responses to extratherapy session events and situations, was related to higher CPTR ratings. As in Session 3, CPTR in Session 6 is maximized when the therapist shows particular interest in the client (and minimized when the focus is on her significant others), but more specifically on her extratherapy cognitive reactions and coping strategies. Starting off on the right foot seems important in Session 6, because therapist behavior is relatively insignificant as a predictor of CPTR in the middle and late phases of this session.

Similarly, in the final therapy session, therapist behavior is strongly related to RI-G ratings only in the early phase. At that point, a focus on the client and not on her significant others, with the therapist talking relatively little and largely reflecting back the client's messages, and with little direct support explicitly communicated to the client, were predictive of higher RI-G ratings. At the middle time point, a focus on cognitions was optimal, and in the final part of the final session, "I" statements were the sole predictor of positive CPTR. This suggests that therapists enhanced CPTR in Session 8 by taking actions that facilitated a smooth and, for the client, complete transition between therapy and termination: allowing the client to take charge and wrap-up any un-

finished business that she might have; not attempting to belatedly bolster the client's self-perceptions through supportive statements; dealing with the client's expectations, concerns, and fears; and providing personalized feedback to the client.

Thus, consistent with past research in a nonbehavioral therapy context (e.g., Barrington, 1961), the pattern of therapist behaviors that emerged as predictive of CPTR was not static; it changed systematically from session to session. Clearly, therapists must tailor their style of interaction to fit the changing goals and needs of the client at different time points in therapy.

These data suggest a potential explanation for why clients' RI-G ratings varied from session to session, and why RI-G scores were differentially effective as predictors of different outcomes at different time points in therapy. The data do not support the possibility that clients were basing their RI-G ratings on the same therapist behaviors in each session and that their therapists simply behaved very differently in different sessions: With one exception (i.e., a focus on significant others was detrimental to CPTR in all sessions), RI-G ratings were associated with different patterns of therapist behaviors in each session and at different time periods.

A more plausible explanation is that clients based their RI-G ratings on how well the therapist and the therapy were fulfilling their expectations, and that different factors influenced the clients' expectations at different points in therapy. Early in therapy, a global good-bad therapist/therapy dimension that has been hypothesized based on empirical data by previous researchers (cf. Mitchell et al., 1977), and that has little to do with subsequent client gains, but that serves as a basis for the client to either stay in or drop out of therapy seemed to be most important—hence, the importance of such behaviors as nonverbal style and emphasis on a collegial client-therapist relationship at this point. At the mid to late portion of therapy, CPTR seemed to be largely a function of the gains that the client saw herself making toward her objectives (i.e., becoming more assertive and less anxious in extra

therapy social situations). The therapists seemed to enhance, and perhaps elicit, these positive self-perceptions by encouraging the client to discuss her successful attempts at assertion from the past week and the cognitions that accompanied such occurrences. Finally, in the last therapy session, RI-G scores appeared to assess the client's feelings about ending therapy. Those who felt finished and ready to move ahead on their own gave high ratings, whereas those who felt unready to end the supportive relationship expressed this fear and dissatisfaction through low RI-G scores. Therapist actions that prevented the latter and facilitated the former cognitive set (e.g., allowing the client to deal with the issues that she feels are essential, giving meaningful feedback) enhanced CPTR. The significant inverse relationship between RI-G scores for Sessions 6 and 8 seems to have occurred because some of the clients who experienced significant gains in therapy (and thus tended to give high RI-G ratings during Session 6) were nevertheless not ready to terminate therapy and therefore gave lower RI-G ratings in Session 8. Conversely, some of the clients who did not make significant gains (and who gave low CPTR ratings in Session 6) were simply insufficiently assertive to resist the strong "hello-and-goodbye" demand characteristics that generally accompany the end of therapy or simply adjusted their expectations and self-perceptions so that despite failing to make significant changes, they did indeed feel ready to leave therapy. A scan of the data for individual clients supported this explanation: 80% of the clients increased or decreased their RI-G ratings from Session 6 to Session 8, and they were relatively evenly distributed in four groups paralleling those hypothesized (i.e., some clients who made significant gains increased their RI-G ratings while some lowered them; similarly, some clients who failed to improve significantly in therapy raised their RI-G ratings and others lowered them).

Clearly, more detailed research must evaluate these hypotheses before they can be considered as more than speculative. In particular, a more direct assessment of the factors that are hypothesized as bases for the client's

RI-G ratings at different points in therapy is necessary (e.g., in addition to administering the RI-G, clients could be asked specifically about their global evaluations of the therapist and therapy, their perceptions that they were benefiting from therapy, and their readiness to end therapy). Further refinement of the therapist behavior code is another important future direction to eliminate the need for a priori groupings of the separate therapist behavior code variables. The measures that contributed most to the prediction of CPTR would seem to be excellent foci for such research (e.g., significant others, non-verbal quality, we statements, cognitions). Also, other potential determinants of CPTR must be examined in light of the finding that therapist behavior rarely accounted for as much as 50% of the variance in RI-G scores (e.g., client expectations and self-perceptions; the nature of the client-therapist interaction; and therapist characteristics).

To conclude, this study has demonstrated that CPTR is an effective predictor of dropping out and *short-term* client gains in a behavior therapy context. Differences among individual therapists contributed significantly to variance in CPTR, but therapy type and session did not. Further, a set of specific therapist behaviors, which were remarkably similar to those postulated by Rogerian clinicians (Mitchell et al., 1977), were found to be predictive of positive CPTR. The limitations of this study mandate its replication before the results can be considered as definitive, yet the importance of the therapeutic relationship in behavior therapy seems clear. However, it must be recalled that CPTR was never an effective predictor of the fundamental criterion of therapeutic effectiveness: *long-term* client gains. We cannot rule out the possibility that in view of the potential reactivity of the self-report and role-playing measure of outcome (Ciminero, Calhoun, & Adams, 1977), the strong demand characteristics implied by a facilitative therapist may have been responsible for the pre-post client gains that were related to CPTR. The fact that several outcome measures showed a correlation with CPTR militates against but does not rule out this hypothesis. CPTR thus appears to facilitate the process of change in

behavior therapy, but it is clearly not a sufficient basis for fully effective intervention.

Effects of Aging, Organicity, Alcoholism, and Functional Psychopathology on WAIS Subtest Profiles

John E. Overall, Norman G. Hoffmann, and Harvey Levin

Department of Psychiatry
University of Texas Medical Branch, Galveston

Multivariate analysis of variance was used to examine the independent effects of several factors on Wechsler Adult Intelligence Scale subtest patterns. A discriminant function contrasting organic brain syndromes with lesser functional psychiatric disorders was defined. Alcoholic patients were found to occupy a position close to the organic brain syndrome group on that continuum. Aging was associated with deficits in specific subtests, whereas the organic brain syndrome pattern involved more generalized deficits.

The primary purpose of this investigation was to examine the similarities and differences in Wechsler Adult Intelligence Scale (WAIS) profile patterns for various organic and functional psychiatric diagnostic groups, with the effects of several other relevant factors controlled statistically. In recent years, there has been increasing interest in the nature of changes in patterns of intellectual abilities associated with aging and with various organic and functional disorders, but the effects have seldom been clearly separated. Most authors agree that in cross-sectional studies at least, age decrements in intellectual performance begin to appear rather early (Jones, 1959; Wechsler, 1958). Such age-related changes tend to be confounded with the changes that are produced by disease states, which are also differentially age related.

The potential diagnostic contributions of the WAIS have been said to range from the differentiation between primary depression and the mood alterations that are frequently associated with senile dementia (Post, 1975) to the discrimination between patients with

Alzheimer's disease and those having a strictly functional psychiatric disorder (Malamud, 1975). The possible differential diagnostic significance of the WAIS in elderly patients is supported by the findings of a number of other investigators who have correlated changes in WAIS profile patterns with estimated degree of cerebral integrity (Thompson, 1976), slowing of dominant frequency of the electroencephalogram (Wang, 1973), and with reduced cerebral blood flow (Wang, Obrist & Busse, 1970). Most studies suggest that the Performance subtests that correspond to the factor of "perceptual organization" (Cohen, 1957) are particularly sensitive to neurologically based intellectual deterioration in elderly patients. A problem with interpretation of such results is that aging, from very early on, produces pattern changes in the absence of any evidence of neuropathology. In most studies, the effects that have been reported in elderly patients suffering from neurological disfunctions of one type or another are almost certainly confounded with the effects of normal aging, even though age-group norms have frequently been considered.

Somewhat different from the question of diagnostic utility is the hope that subtle differences in profile patterns can lead to a better understanding of the nature of cognitive, perceptual, and phenomenological deficits experienced by psychiatric patients. Overall and Gorham (1972) questioned

This work was supported in part by U.S. Department of Health, Education, and Welfare Grant DHEW 5 R01 MH14675-10.

whether the impairment present in normally aging individuals is similar to that observed in patients with diagnoses of chronic brain syndrome. Using the method of multiple discriminant analysis with WAIS subtest profiles, they found that normally aging individuals seemed to differ on one dimension, whereas the chronic brain syndrome patients differed from the normal aging groups along a separate dimension. Specifically, in the institutionalized samples that they studied, simple aging produced greater pattern variability, whereas old patients with chronic brain syndromes evidenced a more general deficit that was reflected in both Verbal and Performance subtests.

Subsequently, Williams, Ray, and Overall (1973) used the WAIS aging and organicity functions defined in Overall and Gorham (1972) to investigate the nature of possible subtle changes in the phenomenological world of the alcoholic patient. They questioned whether the preclinical changes associated with alcohol abuse are more consistent with accelerated mental aging or with a developing organic brain syndrome. They found that the WAIS subtest profiles for alcoholics in a state hospital sample deviated from age norms along both the mental aging and organicity dimensions. Such findings are compatible with other work involving the effects of chronic alcohol abuse in intellectual functioning (Matarazzo, 1972).

The present study attempts to use a more appropriate and powerful multivariate statis-

tical method to separate out and clarify the nature of WAIS profile pattern changes that are associated with chronic organic brain syndrome, alcoholism, and various functional psychiatric conditions independent of the effects associated with aging and with background factors that might also contribute to apparent diagnostic group differences. The need for such complex statistical methods arises because diagnostic groups differ in average age and in other factors that are known to affect WAIS profile patterns. Left uncontrolled, such factors can produce differences in the WAIS profile patterns that are in no way characteristic of the disease processes themselves.

A multivariate analysis of variance (MANOVA) procedure was used to partial out the effects of several partially confounded nuisance variables, to estimate the WAIS profile patterns typical of diagnostic groups with age held constant, and to estimate the effects of simple aging with diagnostic group differences held constant. The prototype for the MANOVA is a factorial design with equal numbers of subjects in all cells. The equal cell frequencies ensure that the effects of any particular factor, such as age, are equally represented in each diagnostic group. In practice, it is not necessary to have each factor balanced with regard to presence in the various levels of each other factor. A nonorthogonal design can be analyzed by least squares regression methods to obtain estimates of the same effects that would be observed in a balanced (orthogonal) design involving the same factors (Overall, Spiegel, & Cohen, 1975).

Table 1
Twelve Major Diagnostic Groups and Their Frequencies

Diagnosis	n
Organic brain syndrome	29
Drug abuse	13
Alcoholic	29
Paranoid schizophrenia	43
Schizophrenia	52
Manic	20
Schizoaffective—manic	16
Schizoaffective—depressed	41
Psychotic depression	29
Depressive reaction	91
Situational reaction	33
Personality disorder	18

Method

WAIS subtest profiles for a sample of 414 psychiatric patients were obtained from the files of the Psychometric Laboratory at the University of Texas Medical Branch. Final clinical diagnoses were used to group the patients into 12 major diagnostic categories, as listed in Table 1. The organic group is of special interest in this investigation, since it represents a generally younger and somewhat less chronic sample with regard to the question of differences between mental aging and organicity than previously studied by Overall and Gorham (1972). The organic brain syndrome group in the present case includes patients who were given diagnoses of either

Table 2
Summary of Tests for Main Effects in a Five-Way MANOVA Design

Variable	Hotelling trace		Wilk's Λ	Pillai-Bartlett	
	χ^2	df		F	df
Age	142.16	33	.6942	4.19**	33, 1158
Ethnicity	118.37	22	.7376	5.56**	22, 770
Sex	84.50	11	.8045	8.48**	11, 384
Parental SES	39.86	22	.9026	1.80*	22, 770
Diagnosis	204.25	121	.5951	2.33**	121, 4334

chronic or acute organic brain syndrome, but all were either newly admitted inpatients or outpatients who were referred for diagnostic testing. No focal lesions, trauma, or temporal lobe epilepsy diagnoses were included.

The independent effects of age and diagnosis were of primary interest in the analyses of the WAIS subtest profiles for these psychiatric patients. Sex and race of the patient and social class of the patients' parents were selected as control variables that should substantially affect the expected IQ and profile pattern without being influenced by the cognitive abilities or clinical status of the patient. The desire was to control statistically for premorbid differences so that the actual effects of age and psychopathology could be seen more clearly without partialing out anything that might represent an effect of the variables of interest. A five-way Age \times Race \times Sex \times Socioeconomic Status (SES) \times Diagnosis MANOVA was used to test the effects of each factor independent of effects on WAIS profile patterns that might be attributed to other factors in the design. Univariate analyses of variance were also

calculated for each WAIS subtest using the same five-way design. A computer program by Woodward and Overall (1974) was used to accomplish the multivariate and univariate analyses in a single pass.

Results

The MANOVA resulted in the recognition that age, race, sex, and SES all have highly significant independent effects on WAIS subtest profiles and that WAIS subtest profiles for the 12 clinical diagnostic groups differ significantly after the effects of the other factors are partialled out. A summary of results from the tests of main effects in the five-way MANOVA is presented in Table 2. Three different test statistics are shown for each effect: an approximate chi-square test based on the sum of all roots of the $|B - \lambda W|$

Figure 1. Configural relationships among diagnostic groups (organic brain syndrome, 1; drug abuse, 2; alcoholic, 3; paranoid schizophrenia, 4; schizophrenia, 5; manic, 6; schizoaffective—manic, 7; schizoaffective—depressed, 8; psychotic depression, 9; depressive reaction, 10; situational reaction, 11; and personality disorder, 12.)

$= 0$ determinantal equation (Hotelling, 1951), a chi-square test based on Wilks' likelihood ratio criterion lambda (Wilks, 1932), and the Pillai-Bartlett F approximation (Olson, 1976). The latter test is widely accepted as best for MANOVA purposes, although in the present case all tests lead to the conclusion that each factor has a highly significant independent effect on WAIS subtest profiles.

Adjusted mean subtest profiles for patients in the four age groups are presented in Table 3, together with the univariate F ratios for testing the significance of effects of age on each subtest separately. The interpretation of "adjusted means" in a nonorthogonal design should perhaps be clarified at the outset. The adjusted means are estimates of the means that would obtain if the total sample included equal numbers of males and females, as well as equal numbers in each of the three social classes, the three ethnic groups, and the 12 diagnostic groups. They statistically estimate the same effects that one might otherwise estimate by sampling in such a

manner that all cells in the complex factorial design contained the same N (Overall et al., 1975). It is in this manner that the effects of other factors are balanced out so that the effect of any one factor can be evaluated independently of any confounding with other factors in the design.

It is apparent in Table 3 that age had selective effects on WAIS subtest profiles in the psychiatric population, just as has been reported in the general population. The age effects were pronounced on all Performance tests and on the Similarities subtest of the Verbal section. Age effects were not observed on Information, Arithmetic, and Vocabulary subtests, and there was only a nonsignificant trend toward a decrement in Comprehension and Digit Span. Thus, considering that the Similarities subtest is the only Verbal subtest requiring "fluid intelligence" (Cattell, 1963), deficits associated with aging in the psychiatric population are clearly represented in an increase in the discrepancy between "crystallized" verbal abilities and cognitive-perceptual-motor behavior requiring flexibility, speed, and agility.

Adjusted subtest means for the 12 clinical diagnostic groups are presented in Table 4. In this case, the profiles have been adjusted to reflect a common average age, race, sex, and SES. Independent of age and the other factors, patients in the different diagnostic groups evidenced significantly different WAIS profile patterns. The diagnostic group differences can be seen to be represented in both Verbal and Performance subtests to a greater degree than was true with the age effects. Again, the diagnostic effects represented in these adjusted profiles are associated with psychopathology *independent* of age and other factors. Whereas age effects were absent in the Information, Arithmetic, and Vocabulary subtests, significant diagnostic group differences were present on those subtests, as well as on the Performance subtests, which were also sensitive to age. No significant diagnostic group differences were present for Similarities, which was the only Verbal subtest that was affected by age.

The MANOVA between diagnostic groups is equivalent to a multiple discriminant function analysis calculated on WAIS profiles from

which the effects of age, race, sex and SES have been eliminated. The analysis confirmed that all of the significant group differences were represented in two major dimensions. The sum of all roots of the error-adjusted between-groups matrix was $\Sigma\lambda_i = 217.2$, which can be referred to a chi-square distribution with $p(k-1) = 121$ degrees of freedom. The first and second roots were $\lambda_1 = 79.8$ and $\lambda_2 = 41.4$, with $(p+k-2)$ and $(p+k-4)$ degrees of freedom, respectively. The sum of all remaining roots, after the first two were subtracted out, was $\Sigma\lambda_i = 96.0$, which is approximately distributed as chi-square with 81 degrees of freedom, and was not statistically significant. Thus, the data provide no evidence that more than two dimensions are required.

The configuration of group means in the plane defined by the first two discriminant functions is displayed graphically in Figure 1. The first, or horizontal, dimension contrasts the organic group with several of the least impaired of the functional psychiatric groups. It is defined primarily as a contrast between Information and Vocabulary on the one hand and Arithmetic and Digit Symbol on the other. Individuals who score toward the organic end of this contrast function tend to score low on Arithmetic and Digit Symbol *relative* to their scores on Information and Vocabulary. This interpretation can be verified by calculating the simple contrast from the adjusted group means in Table 4.

The second, or vertical, dimension separates the organic group from the more accelerated schizoaffective, manic, and manic-depressive groups. It tends to emphasize a general deficit in performance of individuals who score toward the organic end of the vertical continuum. If one considers the *sum* of Vocabulary and Digit Symbol scores, rather than their difference, the ordering of diagnostic groups in the vertical dimension can be reasonably well approximated. The ordering in the vertical dimension can be even more closely approximated by the sum of adjusted mean scores on all 11 subtests in Table 4.

In considering the question of a general deficit, as well as the more specific pattern effects, it is important to recognize that the

WAIS subtest profiles in this analysis were adjusted statistically for the effects of age, race, sex, and parental social class. It is difficult clinically to take all relevant factors into consideration in deciding whether a general or specific pattern deficit is present. The aim here is merely to understand what the effects of organic and functional psychopathology are on the cognitive-perceptual-motor performance of psychiatric patients. The results suggest that organic patients manifest a general impairment, which is most marked on tasks requiring perceptual-motor speed and agility. As compared with other types of psychopathology, moderate hypomania appears to have a less detrimental effect on WAIS performance.

It is interesting to note the proximity of the alcoholic group to the clinically organic group in the WAIS subtest space. None of the alcoholic patients had a clinically recognizable organic brain syndrome; yet, as a group they ranked next to the organic brain syndromes on both the specific (horizontal) and general (vertical) dimensions of deficit. Again, it would be difficult to evaluate such trends clinically because of the need to control for other factors that influence WAIS performance; however, the results do suggest that WAIS profile patterns are sensitive to subtle pre-clinical changes associated with alcohol abuse and that the brain syndromes that occur as end points in alcoholism are not precipitous outcomes.

Ethnicity and sex of patients and social class of patients' parents were included primarily as control variables to adjust statistically for major premorbid differences that should not be confused with the effects of age or psychopathology. As a consequence, the results pertaining to the effects of those factors will be discussed only very briefly. It should be noted that educational achievement was not partialled out because it is in part a result of IQ.

The total patient sample was subclassified as white, black, and Mexican American. Two significant dimensions were found to separate the three groups in the WAIS subtest space after the effects associated with age, sex, parental SES, and clinical diagnosis were partialled out. The first major dimension sepa-

rated the three groups in the order white, Mexican American, and black. It was a general factor that correlated highly with the total score on all subtests. The second discriminant function separated Mexican Americans from the other two groups, and it tended to be a contrast between Verbal and Performance subtests, with the Mexican Americans scoring relatively better on the Performance subtests than on the Verbal subtests.

Sex differences were apparent in this psychiatric population after adjustment was made for age, race, parental SES, and clinical diagnosis. Males scored significantly higher on Information, Arithmetic, and on all Performance subtests except Digit Symbol. Females did not score significantly higher on any subtest.

Social class of parental home was taken from a history form completed by the psychometrists who did the testing. Although it was routinely inquired about, there is some concern that inferences based on social achievement of the patients themselves may have crept into the scoring of this item. Social class was scored as lower, lower middle, or middle, and upper. After adjustment was made for age, race, and diagnosis, the effect of the SES factor was highly significant on all subtests. A single significant dimension separated the groups in the anticipated order, with Information and Vocabulary being the two most discriminating variables.

The multiway MANOVA provided evidence that diagnostic groups differ in WAIS profiles independently of age and that age groups differ independently of diagnosis. It did not, however, provide a basis for concluding whether the *pattern* of effects produced by aging is different from the pattern associated with organic brain syndrome. Neither of the two discriminant dimensions in Figure 1 can be considered to be *the* organicity dimension, since the organic brain syndrome group differed from the other groups along both dimensions. A 45-degree rotation of the horizontal axis in Figure 1 was used to define a function that tends to separate the organic group from all other groups along a single dimension in the age-corrected WAIS subtest space. The MANOVA directly provided a single age function in the diagnosis-corrected WAIS

subtest space. The weighting coefficients defining these two discriminant functions are presented in Table 5.

Further attention can now be directed to whether mental aging and organicity involve similar or different profile pattern effects in the psychiatric population. It has already been noted in Table 4 that diagnostic groups differed significantly on certain Verbal subtests that were not significantly affected by age as shown in Table 3. Examination of the weighting coefficients in Table 5 reveals that the aging function is more clearly a contrast between Verbal and Performance subtest scores, whereas the organicity function contrasts subtests within the two major domains. The largest effect of both aging and organicity was on the Digit Symbol subtest; however, low Vocabulary and Digit Span scores were positive indicators for organicity but negative indicators for mental aging independent of diagnosis. The variability in profile pattern, and therefore the variability of weighting coefficients in the discriminant function, is greater for mental aging effects than for the effects of organic brain syndrome.

From a conceptual/interpretative point of view, the results can be understood by considering the age effect to increase *pattern variability* through reduction in "fluid intelligence" scores and the organic brain syndrome effect to represent a more general *global deficit*. The age groups order in a similar manner in both dimensions because the "fluid intelligence" deficit, which increases pattern variability, also reduces total scores. The organic brain syndrome effect is almost entirely in the dimension characterized by overall deficit and only slightly in the direction of increased pattern variability.

Discussion

The present study supports earlier work, which indicated that the effects of organic involvement on the cognitive, perceptual, and motor functions in patients diagnosed as having organic brain syndrome are distinct from the effects of the normal aging process.

Differences attributable to aging in this psychiatric sample appeared to fit well into the crystalized versus fluid intelligence con-

Note. WAIS = Wechsler Adult Intelligence Scale.

cept proposed by Cattell (1963), in that older patients tended to show lower scores on those subtests that required mental flexibility and perceptual-motor speed relative to those subtests that tap established or practiced cognitive abilities. In contrast, organic patients manifested a more general deficit in intellectual functioning as measured by the WAIS, as well as a different pattern of relative score deficits.

The thrust of this study has been the investigation of WAIS subtest scores in an attempt to provide some understanding of the nature of defects found in psychiatric patients. As such, it was not intended to directly provide aspects of clinical utility or to support specific clinical approaches. The statistical adjustments made in these analyses are not readily applicable for clinical use. Also, significant results in group data do not necessarily imply sufficient discriminative power for application to individual cases. Yet, the results reported here would appear to have some implications for further work along both theoretical and clinical lines.

One such approach might be the replication of this study on a sample of patients with selected organic and functional disorders in conjunction with more neuropsychological data on the patients. This would facilitate the consideration of specific types of organic involvement and the assessment of apparent cognitive deficits in specific diagnostic groups. As was noted in this study, patients with the

diagnosis of alcoholism appeared most similar to the organic group, even though alcoholics with any definite or possible organic diagnoses were excluded from the sample. Similarly, schizophrenics were also found to be more similar to the organic group than were those with affective psychoses and the less disturbed psychiatric patients. This would perhaps suggest confirmation of the work of Johnstone, Crow, Frith, Husband, and Kreel (1976), who found evidence of enlarged ventricles in the in vivo brains of schizophrenic patients.

The current results showing distinct effects of age support the use of age-scaled standard scores as provided in the WAIS manual or other standardized scores adjusted for age when the WAIS is to be used in the assessment of organicity.

One can also infer differential utility of the 11 subtests in the evaluation of organicity. Some of the WAIS subtests seem more effective in tapping those abilities or capabilities that are diminished by organic impairment. Perhaps a few subtests could be used to answer specific questions relative to specific types of organic involvement. On the other hand, further work might indicate that the WAIS is not readily adaptable to such a task, but other tests or instruments that provide better measurement of the subtle distinctions suggested here can be devised to determine the degree of organic impairment.

Research containing multivariate techniques such as those used in this study may provide increased understanding of cognitive, perceptual, and motor deficits in psychiatric patients. Some efforts may be primarily of theoretical import, but others could make contributions to clinical practices.

Locus of Control in Mexicans and Chicanos: The Case of the Missing Fatalist

David Cole and Jacqueline Rodriguez
Occidental College

Shirley Cole
University of Arizona

We studied the extent to which a stereotype of Mexican or Chicano students as fatalistic is supported by their locus of control scores. Data came from locus of control scores from male university students in four nations: United States (86), Mexico (57), Ireland (47), and West Germany (54). These data show the Mexican university students to be more internally oriented than students from each of the other nations ($p < .001$). The study also compares locus of control scores for 151 Anglo and 95 Chicano senior high school students from three Southern California high schools. Scores for Chicanos are nearly identical to those obtained from Anglo students. Only Chicano male high school students not planning to enter college showed any tendency toward a more external locus of control ($p < .05$). The article concludes that to the extent a perceived external locus of control would be indicative of a fatalistic outlook, such perception is lacking in most data on Mexican and Chicano respondents.

Recent years have seen several studies allowing transnational comparisons, usually among students, in locus of control measures (Hsieh, Shybut, & Lotsof, 1969; Mahler, 1974; McGinnies, Nordholm, Ward, & Bhanthumnavin, 1974; Parsons & Schneider, 1974; Schneider & Parsons, 1970; Reitz & Groff, 1974). Resulting differences between persons of different nations are then related to different societal structures, socialization patterns, or national traditions or customs. Thus, for example, Hsieh et al. (1969) ascribed the greater externality found among their Chinese respondents, when contrasted to American-born Chinese or Anglo Americans, to differences in outlook that are traditional to Chinese as contrasted with Americans. McGinnies et al. (1974) provided a series of suggestions based on Japanese culture and society for their finding of greater externality

among Japanese respondents as contrasted to those from three nations with an Anglo-Saxon tradition. They suggested that the Swedish social system of maximizing personal security may account for the relatively external scores of their Swedish respondents, but they also noted that the Swedish respondents were younger than those from other national groups in their study.

Among the studies cited above, only that by Reitz and Groff (1974) used other than student respondents. Reitz and Groff focused on locus of control as a function of the degree of economic and industrial development in a nation and used nonsupervisory laborers from the United States, Mexico, Japan, and Thailand as respondents. There were no significant main effects of the state of economic development, although differences did appear on the subscales of the Rotter test (Rotter, 1966). There was a significant main effect when the western nations were compared to the Asian nations, with the western nations being overall more internally oriented. Comparing the United States with Mexico, the Americans were more

This study was adapted from a paper presented at the Rocky Mountain Psychological Association, Phoenix, Arizona, May 1976.

internal on the Leadership subscale and more external on the Luck subscale, with no overall significant differences between persons from the two nations.

The work of Reitz and Groff (1974) is particularly relevant to the present article, because it included persons from Mexico and allowed evaluation of the extent to which such persons may be described as "fatalistic" when compared to respondents from other nations. The present study, which began before the Reitz and Groff (1974) data appeared, is an attempt to evaluate the validity of the stereotype of fatalistic as it applies to Mexican and Chicano students. We were initially moved to a study of this question by two related observations. When discussing the concept of locus of control as it might appear in Mexican and/or Chicano respondents, Anglo friends of ours were usually quick to predict that such persons would score in an *external* direction as contrasted to Anglo Americans, whereas the Chicano who we consulted usually declared that this would be the case.

The importance of this issue should not be understated. Numerous authors (e.g., Berry, 1964; Coon & Makin, 1971; D. Anderson, 1975; Miller, 1966; Justin, 1970; Lewis, 1970; Morales, 1971) have shown that Mexican and/or Mexican Americans who are viewed by Anglos as passive and fatalistic. In general, these authors have not provided extensive empirical support for the stereotype. For example, in their studies of students in U.S. universities, these authors have concentrated on the stereotype that Anglo Americans have of Mexico, Jews or persons from various European countries (e.g., Miller, 1966; Reitz, 1974; & Watters, 1970; Katz & Brady, 1970). To determine if such a stereo-

type exists among American students similar to those studied in this investigation, a sample of 53 students at the liberal arts college (cited in Table 1) were asked to complete the Rotter scale as they believed they would answer if they were Mexican students attending a Mexican university. In contrast to the mean of 5.88 actually obtained from Mexican students, or the mean of 10.15 obtained from American liberal arts students answering for themselves, these "pseudo-Mexican" students produced a mean of 15.55. This is significantly more *external* than the mean of actual Mexicans ($p < .001$) or Americans answering for themselves ($p < .01$). Combining these data with the observations of the several authors cited above, we contend that the presence of a stereotype of Mexicans and/or Mexican Americans as passive and fatalistic is justified. In many geographic areas of the United States, and especially those from which we come, counselor and teacher interaction with Chicano and Mexican students is widespread and daily. There is ample reason to investigate the validity of a stereotype that is likely to influence counselor and teacher prediction of a student's academic behavior.

The contention that perception of an external locus of control would indicate a fatalistic outlook seems warranted by what is implied by such a perception. If one believes, as a person with a perceived external locus of control is presumed to believe, that positive and/or negative events in one's life are beyond one's personal control, this seems clearly to invite, if not define, a fatalistic outlook.

Method

Subjects

For the study reported here, the Rotter Internal-External Locus of Control (I-E) Scale (Rotter, 1966) was administered to male, Catholic, business administration students in the United States, West Germany, Ireland, and Mexico. For use in West Germany and Mexico, the scale was translated into the appropriate language, following procedures recommended by Brulin (1970). The Rotter scale was

The authors wish to express appreciation to Robert Chestnut who arranged for the translation of the scales into German.

first translated into the appropriate foreign language (Spanish or German) by a bilingual psychologist, whose first language is English. The translation was then given to a bilingual colleague, whose first language is Spanish or German, respectively. This colleague translated the scale back into English, without seeing the original scale. Translation was considered accurate when this translation back into English corresponded with the original English version. When results from Mexico proved striking, the translation process was repeated, as a double check on possible errors. No changes were made as a result of this duplication of the initial work. By selecting business administration majors, we obtained students in the four nations who were pursuing highly similar curricula, with similar career goals. In limiting the respondents to those who were at least nominally Catholic, we attempted to control for the potentially relevant variable of religious frame of reference as a factor influencing one's perceived locus of control. When data analysis showed these two variables to be irrelevant, we added a second group of U.S. students, from a liberal arts college, to expand the base of the American sample, but we kept this second group separated from the American business administration students throughout the data analysis. Because sex has been shown to be a variable in I-E scores (McGinnies et al., 1974) and because no females were available from Ireland and very few from West Germany, we confined the sample to males. All scales were administered in the classroom, by native speakers. The Irish sample came from a university in Dublin, the German from a university in the western portion of West Germany, and the Mexican sample from a university in south-central Mexico. The American business administration students came from a private, Catholic university on the west coast, and the liberal arts students came from a private liberal arts college also on the west coast. West German and Irish students were included because they were available to us, and they provided, along with the American data, a much broader base of national groups against which to compare and contrast the Mexican data.

At the outset of the study, the Levenson scale (Levenson, 1974) was not available. It was available by the time we started gathering data from Chicanos, however, and its ready analysis into three separate scales made it worthwhile to use, particularly since direct score comparison with the university student groups was not needed. For the high school portion of the study, the Levenson scale was administered in classrooms to 12th-grade students in three Los Angeles area high schools, one almost entirely Anglo and two almost entirely Chicano in makeup of student population. In the Chicano high schools, three different schedules of administration were used: In some classes a Chicano psychologist administered the scales, in some an Anglo psychologist did so, and in some both administrators were present. Ethnicity of the scale administrator proved irrelevant. All scales in the

Anglo classrooms were administered by an Anglo. In all three schools, data were collected from students in college preparatory curricula and from students not in such curricula.

Results

The results from the testing of university students in the four nations are presented in Table 1.

The mean score for the Mexican respondents was significantly lower than each of the other means ($p < .001$, in each instance). No significant differences were found between the means of any of the other national groups.

Because Reitz and Groff (1974) presented their data in terms of the percentage of externally oriented answers given on each of the five Rotter subscales developed by Schneider and Parsons (1970), we made the same breakdown in analyzing the present data. Our figures are presented in Table 2. Tests for significant differences in proportions were tested by z scores, again following the method of Reitz and Groff. Beyond those cited in Table 2, only one other comparison reached significance. The U.S. liberal arts students scored more external on the Respect subscale than did the West Germans. Except for this, all significant differences attest to the greater internality of the Mexican respondents.

Table 3 presents the data on Mexican laborers as reported by Reitz and Groff (1974), alongside our own data from university students in the United States and Mexico. On each subscale the Mexican students were more internal than the Mexican laborers. Both groups of American students were more internal than American laborers on the Politics subscale and more external on the Respect subscale. One group of American laborers was more external than American laborers on the Leadership subscale, but this did not hold for the other student group.

The Levenson scale provides three scores: internal locus of control, control by powerful others, and control by chance. Scores on each scale can range from -24 to $+24$. Results from the testing of high school students are presented in Table 4.

There are no significant differences, on any of the scales, between Chicano and Anglo

Table 2

Comparisons of Percentage of External Responses by Category

** $p < .02$.

*** $p < .01$.

students. Within ethnic groups, the college-bound Chicano male rejected control by chance more than did his non-college-bound counterpart ($p < .05$). No significant sex differences were found. All of the high school groups, whether Anglo or Chicano, tended to endorse the idea of internal locus of control and to reject the ideas of control by powerful others or chance happenings.

Discussion

This study began as an attempt to evaluate the validity of the stereotype of Mexicans and Chicanos as fatalistic, as that attitude would be expressed through perception of an external locus of control. Clearly, the Mexican university students were *not* more external; indeed, they were significantly more

internal in locus of control than students from three other nations. The finding is not limited to a single time period, for the data were collected at two points in time, about 7 months apart. The results are not limited to the particular instrument, for two of us (Cole & Cole, 1977) have reported a similarly strong emphasis on internal locus of control using the Levenson scale with Mexican students. The data from Reitz and Groff (1974) allow us to note that this is not an artifact of testing students. Their Mexican laborers, although not more internal than American laborers, were not more external either. Indeed, on the Luck subscale, surely the psychological heart of fatalism, both Mexican students and Mexican laborers received their least externally oriented scores. Thus we feel that these data lend no support to, and instead challenge, the stereotype of Mexicans as fatalistic.

Turning to Chicanos, we know of only one previous study that addressed this issue. Garza and Ames (1974) reported that Chicano university students scored in a significantly more internal direction than Anglo students in the same university. Our data for high school students do not show a group difference, but they are striking in the high degree of similarity between the scores from Anglos and from Chicanos. Only the male Chicanos not planning to enter college offered the most tenuous support for a fatalistic stereotype, in their significantly lower rejection of control by chance. Even here however, it is important to note that they did

not embrace chance; they merely rejected it less than other students.

The findings regarding Mexicans and Chicanos seem so at odds with Anglo folk wisdom that a further item analysis seemed indicated. Gurin, Gurin, Lao, and Beattie (1969) have distinguished between perceived locus of control as it applies directly to the self and as a perception of a general, but not necessarily personal, social condition. Consequently, we did an item analysis that contrasted responses to the personally worded items of the Rotter scale with those describing general social conditions. The Mexican students' responses were the same to both types of items. The distinction was not a useful one in this instance.

Secondary findings within the study seem to warrant only brief comment. It does not seem surprising that the Mexican university students scored in a more internal direction than their labor worker compatriots. As young, upwardly mobile students, it follows that they would be more convinced of the efficacy of their actions than their less advantaged compatriots. That this difference would be marked in Mexico and not in the United States may be accounted for by the fact that being a university student in Mexico is a considerably more unique achievement than in this country. Two of us have argued on the basis of other data (Cole & Cole, 1977) that an internal locus of control will be particularly marked in an individual who has taken a counternormative step toward self-improvement. Pursuit of a

university degree in business administration is probably considerably more unusual in Mexico than in the United States.

The greater internality of the American students on the Politics subscale, when compared to scores on that scale for the American laborers, probably can be explained by the same rationale as is offered for the differences between the Mexican students and the Mexican laborers. (The American sample was a pre-Watergate sample.) On the other hand, both American student groups were significantly more externally oriented on the Respect subscale than the American laborers. This difference becomes more easily understood, however, if attention is directed to the content of the four items comprising this scale. Two of them deal directly with the question of how much assurance one can have that one is liked and accepted by one's peers. It is on these two items that the American students showed their strongest external orientation, and thus it seems likely that the external orientation on the Respect subscale obtained from these two American student groups reflects their status as young people still unsure of themselves in peer relationships, an insecurity much less evident in the Mexican students.

Results on the Leadership subscale were inconsistent, with one American group differing from the laborers and the other not. No explanation is offered.

It is of interest to note that the Irish and Mexican student groups share the common property of scoring most externally on the Politics subscale, something not found in the U.S. and West German samples. The political situations facing the Mexican and Irish students at the time of the testing may be of considerable relevance to this finding. The students at the Mexican university were at a school where there was a high degree of political unrest and opposition to the national government and where the data collection was held up several weeks while the school was closed by government order due to fear of student uprising. The Irish students were tested during a time of great tension between the political factions of Ireland, where acts of political terrorism were part of their daily experience. In light of these observations, it

is hardly surprising that these two groups showed more externality on the Politics subscale, and indeed one may wonder that the scores were not more external than they were.

Returning, however, to the chief thrust of this study, evidence to support a stereotype of a Mexican factory worker, a Mexican university student, or a Chicano high school senior as fatalistic, believing that his own actions are irrelevant to personal outcomes, is almost totally lacking. Instead, these groups appear equally or more internal in perceived locus of control than their American counterparts or other groups with whom they have been compared.

A Multiple-Component Treatment Approach to Smoking Reduction

Charles H. Elliott and Douglas R. Denney
University of Kansas

A package treatment program was designed to reduce cigarette smoking, and its effectiveness was compared with a single treatment condition (rapid smoking), a nonspecific treatment condition, and an untreated control condition. Following the treatment and posttesting sessions, another factor was introduced. One third of the subjects in each of the three treatment conditions were randomly assigned to specific booster (i.e., additional rapid-smoking) sessions, nonspecific booster sessions, or no booster sessions. Since the principal issue in the treatment of smoking is the maintenance rather than the induction of change, emphasis was placed on follow-up smoking levels 3 months and 6 months after the termination of treatment. The package condition was shown to produce substantially higher abstinence rates (45%) and lower percentages of baseline smoking (41%) after 6 months than the other treatment and control conditions. No reliable effects due to booster sessions were found.

Several reviews of the smoking reduction literature (Bernstein, 1969; Bernstein & McAlister, 1976; Hunt & Belpalec, 1974; Hunt & Matarazzo, 1973; Lichtenstein & Danaher, 1976; McFall & Hammen, 1971) have reached the following conclusions: (a) Virtually any treatment program is capable of reducing smoking levels to 30% or 40% of baseline; (b) a return to about 75% of baseline is commonly observed from 3 to 6 months after treatment; (c) seldom more than 13% of the subjects in any treatment program are completely abstinent after a 3- to 6-month follow-up period; and (d) of those subjects who are abstinent at the end of treatment, less than one third manage to maintain non-smoking 3-6 months later. High relapse rates have been observed for a wide variety of behavioral techniques, including systematic desensitization (Pyke, Agnew, & Kopperud,

1966), rapid smoking (Lando, 1975, 1976; Lichtenstein, Harris, Birchler, Wahl, & Schmahl, 1973; Schmahl, Lichtenstein, & Harris, 1972; Sutherland, Amit, Golden, & Rosenberger, 1975), covert sensitization (Sachs, Bean, & Morrow, 1970) aversive conditioning (Berecz, 1972; Whitman, 1972), stimulus control (Bernard & Efran, 1972), contingency contracting (Lawson & May, 1970), and behavioral rehearsal (Steffy, Meichenbaum, & Best, 1970).

The striking uniformity in these results generated by diverse techniques led McFall and Hammen (1971) to hypothesize that nonspecific factors were responsible for most of the reported changes in smoking rates. They designed a treatment procedure that incorporated only nonspecific factors such as motivated volunteering, self-monitoring, expectancy, demand, and mild encouragement. The procedure resulted in reduction rates and abstinence figures comparable to the figures cited above. Lichtenstein and Keutzer (1971) have argued that since smoking responds so readily to nonspecific factors, at least temporarily, minimal or nonspecific treatment groups constitute more adequate controls than do untreated groups in smoking reduc-

This research was funded by a University of Kansas general research grant awarded to the second author.

tion outcome studies. Unfortunately, most of the above studies have failed to include non-specific treatment groups in their design.

Although initial studies focused on the effectiveness of single treatment procedures, attention now appears to be shifting to broad-based package therapies for treating maladaptive behaviors such as smoking (Lichtenstein & Danaher, 1976), alcoholism (Denney, 1976), and obesity (Mahoney, Note 1). Two basic arguments can be cited in favor of package approaches to treatment. First, the multi-determined nature of these maladaptive behaviors is becoming increasingly apparent. As investigators learn to appreciate the complexity of these behaviors and the variety of functions that cigarettes, alcohol, and food can serve for each individual, the necessity of package approaches that use a variety of techniques becomes clear. Second, from a strategic point of view, it would seem advisable to devise a complex treatment program that achieves the desired results in terms of bringing about persistent changes in these maladaptive behaviors and then subsequently to perform analytical studies to discover the effective components operating within the package. The current research on the reduction of smoking lacks clear demonstrations of long-term effectiveness. Only after such effects have been produced can the isolation of effective component procedures be undertaken.

Lichtenstein and Danaher (1976) surveyed the initial package approaches to smoking reduction and concluded that their effectiveness was no greater than single approaches. Five additional package approaches have since appeared in the literature and have generally indicated more encouraging results. Best (1975) evaluated a treatment package that was tailored to subjects' locus of control scores and included rapid smoking, aversive conditioning, attitude change techniques, and a review of environmental determinants of smoking. Best reported smoking levels at 30% of baseline and abstinence rates of 50% 6 months after treatment. Pederson, Scrimgeour, and Lefcoe's (1975) treatment package included hypnosis, relaxation training, self-monitoring, rehearsal of alternative behaviors, self-management training, and discussion. These investigators found that 50% of their

subjects were abstinent 6 months after treatment. Delahunt and Curran (1976) developed a package combining self-control and negative practice procedures. A 6-month abstinence rate of 56% for the nine subjects in the package condition was reported. Lando (1977) reported a 76% abstinence rate 6 months after administering a treatment package that included aversion, contractual management, booster sessions, group contact, and support. The one exception to these more encouraging results that adheres to package approaches is a study by Danaher (1977). His package approach, which combined rapid smoking with a variety of self-control procedures, resulted in abstinence rates of 21% and smoking levels of 52% of baseline after a 13-week follow-up. Furthermore, the package treatment in this final study was actually less effective than a procedure involving rapid smoking alone.

Danaher's (1977) pessimistic findings regarding package approaches are especially disturbing, since his study corrected for a number of methodological weaknesses in the preceding studies. All four of the preceding studies used single therapists who were aware of the hypotheses under investigation, thus augmenting the chances of experimenter bias. Three of these studies (Best, 1975; Lando, 1977; Pederson et al., 1975) failed to include nonspecific treatment groups, and, as Lichtenstein and Keutzer (1971) have argued, these groups represent the preferable form of control for smoking reduction studies. The data collection procedures used in three of the studies (Best, 1975; Delahunt & Curran, 1976; Pederson et al., 1975) relied exclusively on subjects' own counting of the number of cigarettes consumed or on their estimated rates of smoking, with no systematic attempts to check on the accuracy of these data. Finally, Lando (1977) required subjects to attend additional sessions of aversive treatment if they returned to smoking after treatment, a practice that clearly could lead to inflated results at follow-up.

The present study was designed to evaluate a broad-based treatment package for the reduction of smoking and to compare its effectiveness with a single treatment procedure (rapid smoking), which constituted a major

component within the treatment package. Thus, the results of this study are directly comparable to those reported by Danaher (1977). Like Danaher's investigation, the present study incorporated several methodological refinements including (a) multiple therapists; (b) a nonspecific treatment procedure, including information and group discussion along with the usual nonspecific factors accompanying any treatment; and (c) checks on the accuracy of subjects' cigarette consumption data. The selection of components for the current treatment package was based on research examining the effectiveness of each component as a single treatment procedure for reducing smoking. In particular, the treatment package was designed to enhance the maintenance and generalization of treatment effects by emphasizing the use of general, self-initiated coping strategies.

A second purpose of the present study was to evaluate the use of booster sessions for improving the maintenance of smoking reduction. Although several investigators have recommended the use of booster sessions and have incorporated such sessions in their treatment procedures (Chapman, Smith, & Layden, 1971; Hunt & Matarazzo, 1973; Lando, 1975, 1977; Lichtenstein et al., 1973; Schmahl et al., 1972), only one controlled investigation of the effectiveness of booster sessions has been reported. Kopel (1974) found no differences between subjects who received rapid-smoking booster sessions following treatment procedures involving rapid smoking and subjects who had received no such booster sessions. The design of the present study allowed us to compare subjects who had received specific booster sessions consisting of additional rapid-smoking trials, subjects who had received nonspecific booster sessions consisting of additional information and encouragement, and subjects who had received no booster sessions.

Method

Subjects

Newspaper advertisements were used to recruit smokers from the community of Lawrence, Kansas. To be accepted into the study, subjects had to be smoking at least 10 cigarettes per day and be willing to pay a \$30 deposit that would be returned to them

gradually over the course of the study, contingent only on their attendance at treatment and follow-up sessions. Of the 108 persons who attended an introductory session, 69 complied with these requirements and agreed to participate in the study.

Because of possible health hazards associated with rapid smoking (Hauser, 1974; Lichtenstein, 1974), subjects were required to complete a medical history questionnaire and to have their weight and blood pressure measured. Five subjects were dropped from the study because of possible health complications. One additional subject was dropped later in the study because of failure to faithfully use the cigarette collection method.

Pretest and posttest data were therefore available for 63 subjects (29 males, 34 females). This sample had the following characteristics: average age = 29.4 years; average education = 15.7 years; average length of time smoking = 12.4 years; average estimate of daily smoking level = 27.0 cigarettes; and average daily number of cigarettes smoked during a 7-day baseline period = 19.6 cigarettes. The number of subjects in the package treatment, rapid-smoking treatment, nonspecific treatment, and untreated control conditions were 20, 19, 18, and 6 respectively.¹ Three additional subjects were lost during the 6-month follow-up period, 1 each from the rapid-smoking treatment, nonspecific treatment, and control conditions.

Pretesting

A pretest session was conducted 1 week prior to treatment. During this session, all subjects completed two questionnaires. The smoking history questionnaire was designed to provide information descriptive of the subject sample and to obtain the name and phone number of a close friend to help check on the accuracy of the cigarette collection method. The semantic differential scale was designed to assess subjects' attitudes toward smoking. The concept *cigarette smoking* was rated on 10 7-point scales comprised of highly evaluative bipolar adjectives (e.g., healthy-unhealthy; attractive-ugly; soothing-irritating; fragrant-rank).

After completing these questionnaires, subjects were given a stack of cloth pouches, similar in design to tobacco pouches, in which to store their cigarette butts. Subjects were explicitly told not to count their cigarettes but simply to drop their butts into the pouches, using a new pouch each day.² The next 7 days prior to the first treatment session con-

¹ Since the subjects in the three treatment groups were later divided into subgroups receiving specific booster sessions, nonspecific booster sessions, and no booster sessions, the number of subjects in the untreated control group was similar to those of the other nine cells in the complete design.

² Pilot testing had shown that subjects would follow these instructions without counting the number of butts in the pouch.

stituted the baseline period during which the first count of cigarette consumption was completed.

Treatment

Following the pretest session, male and female subjects were assigned separately to four conditions: package treatment, rapid-smoking treatment, nonspecific treatment, and untreated control. Each of the three treatment conditions was administered to groups composed of 6-9 subjects. The subjects in these three treatment conditions attended three treatment sessions per week for 3 weeks. All subjects continued to collect their cigarette butts and to turn them in periodically during the 3 weeks of treatment.

Five advanced undergraduate psychology majors (three males, two females), served as therapists. One female therapist was responsible for the nonspecific procedure, which included giving brief informative lectures about smoking, handing out educational materials, collecting cigarette pouches, and giving mild encouragement. This nonspecific procedure was conducted for all subjects at the start of each treatment session, after which the subjects went to other rooms to receive their specific treatment procedures. Accordingly, throughout the study this therapist was unaware of the treatment conditions to which subjects had been assigned. The remaining four therapists were unaware of the hypotheses under investigation, and the treatment procedures they dispensed were highly standardized, with many components being presented by tape recorders.

At the first treatment session, subjects were told that they could attempt to quit smoking either immediately or gradually. The importance of accurate data collection was emphasized, and subjects were told that lie detector tests would be used at the end of the study to corroborate their conscientious use of the pouches. A brief description of each condition follows.³

Package treatment. In addition to the nonspecific procedure, eight component procedures were included in the package treatment. A rapid-smoking procedure (Lichtenstein et al., 1973) required subjects to smoke every 6 sec until they were unable to continue. Two rapid-smoking trials were presented during each treatment session. In the *applied relaxation* procedure (Chang-Liang & Denney, 1976), subjects practiced relaxation exercises while seated in a private cubicle listening to tape-recorded instructions. Subjects were also instructed in the application of relaxation as a coping skill during times when they felt a desire to smoke. The *covert sensitization* procedure (Gerson & Lanyon, 1972) encompassed both aversive scenes and relief scenes. In the former, subjects visualized themselves starting to smoke a cigarette in a particular setting, becoming nauseous, and vomiting. In the relief scene, subjects imagined themselves turning away from cigarettes and making some covert self-assertion ("I can control this habit"), whereupon the imagined feelings of nausea subsided. In the *systematic desensitization* procedure (Gerson & Lanyon, 1972), subjects were instructed to relax

and to imagine scenes involving situations that commonly elicited smoking. Six hierarchically ordered scenes were used in this procedure. The scenes had been selected on the basis of responses from a previous sample of smokers who responded to a survey concerning settings that commonly elicit smoking behavior. In the *self-reward and punishment* procedure (Thoreson & Mahoney, 1974), subjects completed contractual forms describing rewards and punishers that they would deliver to themselves contingent on their reaching or not reaching a self-selected smoking rate. In *cognitive restructuring* (Reed & Janis, 1974), subjects listed typical rationalizations as to why it was difficult for them to stop smoking. Later they were taught to formulate alternative ways of thinking about each rationalization and to use new self-verbalizations whenever tempted to smoke. *Behavioral rehearsal* (Chapman et al., 1971) involved practicing both verbal responses for turning down cigarettes in a variety of social settings and nonverbal behaviors (e.g., rubbing two coins together) as substitute activities during times when one was tempted to smoke. In *emotional role playing* (Janis & Mann, 1965), subjects prepared and then enacted scenes in which they learned that they had lung cancer and had to inform loved ones of their impending death.

In general, the package treatment introduced a wide variety of procedures rather than exhaustively dealing with each one. Table 1 illustrates the order of presentation and the approximate time devoted to each component procedure in the package condition during the nine treatment sessions.

Rapid smoking. This treatment was patterned after the rapid-smoking treatments described by Lichtenstein (Lichtenstein et al., 1973). Following the nonspecific procedure, subjects in this condition received two rapid-smoking trials conducted like those described for the package treatment. This sequence was repeated during each of the nine treatment sessions.

Nonspecific treatment. Subjects in this condition received the standard nonspecific procedure, including lectures, educational materials, mild encouragement, and data collection. To equate this condition with the preceding two conditions in terms of both time and plausibility, the subjects engaged in non-directive discussion for about 45 minutes following the standard nonspecific procedure.

Untreated control. Subjects in this group collected their cigarette butts and engaged in the pretest, posttest, and follow-up sessions, but they received no intervening treatment. They were told that they could use any of their own efforts to quit smoking during the data collection period.

Posttesting

The posttest session was conducted 1 week after the last treatment session. Subjects turned in the

cigarette butts collected over the 7 days subsequent to their last treatment and once again completed the semantic differential scale. Pouches for the week prior to the 3-month follow-up session were distributed.

Booster Sessions

Following the posttest session, subjects in each of the three treatment conditions were randomly divided into three booster conditions. Subjects as-

signed to the *specific booster* condition received three booster sessions, each of which included a brief refresher lecture, mild encouragement, and two additional rapid-smoking trials. Those in the *nonspecific booster* condition received three booster sessions consisting simply of the refresher lectures and mild encouragement. Those in the *no-booster* condition received no contact between the posttest and the first follow-up sessions. Booster sessions were conducted during the 1st, 3rd, and 5th weeks after the posttest session.

3-Month and 6-Month Follow-Up

Three months after the posttest session, subjects were contacted by phone and were reminded to begin using their collection pouches for the next 7 days. They were also asked to estimate their daily smoking level. One week later the subjects returned to the laboratory to turn in their pouches and complete the semantic differential scale.

The second follow-up, conducted 6 months after the posttest, was identical to the first. After the pouches had been collected and the questionnaire was completed, all subjects were debriefed and their deposits were returned. Untreated subjects and those who were not satisfied with their progress in the treatment conditions were offered additional individual treatment.

Data Accuracy Checks

It was possible to obtain the help of a friend for 56 of the subjects. The friend agreed to observe whether the pouches were being used conscientiously by the subject. These friends were contacted once during the treatment sessions and once during each follow-up session. Their reports resulted in the exclusion of only 1 subject's data.

As an additional check on the data, 55 subjects were contacted by phone 4 days after the second follow-up session. Using a nonreactive measure inspired by Sushinsky (1972), a confederate attempted to conduct a marketing survey in which the subject was asked to report on the quantity of several nonfood grocery items consumed. One item in the survey was cigarettes. Forty-six subjects agreed to take part in the survey. Two were later eliminated because they suspected a connection to the smoking study. In no instance did the estimates given by the remaining subjects vary more than 20% from either the smoking level estimates or the actual pouch count collected during the second follow-up session. Most importantly, not one of the subjects who claimed to be abstinent admitted to smoking during the nonreactive call.

Results

Preliminary Analyses

A number of preliminary analyses of variance were performed on the data, producing

Figure 1. Cigarette consumption as a percentage of the baseline level of smoking.

the following results: (a) No significant differences were found among subjects in the four conditions (i.e., package, rapid smoking, nonspecific, untreated control) in terms of age, years of education, years of smoking, estimated motivation to quit, estimated daily smoking level, or locus of control; (b) no significant initial differences existed among subjects in the four conditions in terms of any of the repeated measures, that is, baseline smoking level or attitudes toward smoking; (c) no significant differences existed among subjects in the three treatment condition (i.e., package, rapid smoking nonspecific) in terms of expectancy of success as measured by a five-item expectancy questionnaire administered during the first treatment session; (d) no significant main effects for sex and no significant Sex \times Condition interactions existed on any of the measures described above; and (e) no significant main effects for sex and no significant Sex \times Condition interactions were found in terms of outcome on the two repeated measures. Accordingly, the four conditions were considered equal at the start of treatment, and sex was eliminated as a factor in all subsequent analyses.

Cigarette Consumption

Percentage of each subject's baseline smoking was used to reflect changes in cigarette consumption. These percentages were considered a more appropriate gauge of treatment outcome than actual numbers of cigarettes smoked and could easily be compared with other treatment studies (McFall & Hammen, 1971).⁴ Figure 1 depicts the changes that occurred in percentage of baseline smoking over the course of treatment, posttest, and follow-up sessions.

A 4 (treatment) \times 4 (trials) analysis of covariance was performed on the percentage of baseline smoking scores for the 3 treatment weeks and the posttest week. The average daily number of cigarettes smoked during the baseline week served as the covariate. A significant Treatment \times Trials interaction was found, $F(9, 177) = 5.96, p < .001$. A series of one-way analyses of covariance and Duncan pairwise comparison tests were performed to further analyze this interaction. Each of the treatment conditions resulted in significant decreases in smoking across trials

⁴ Number of cigarettes smoked was also analyzed and yielded results that were equivalent to those for the percentage of baseline smoking.

(all $ps < .001$), whereas the untreated control condition resulted in no change ($F < 1$). At the time of the posttest, the subjects in the three treatment conditions were smoking significantly less than those in the untreated control condition (all $ps < .005$). Furthermore, the package condition resulted in significantly less smoking than the rapid-smoking condition. The difference between the package condition and the nonspecific condition was not significant, but it did favor the package condition.

A 3 (treatment) \times 3 (booster) \times 3 (trials) analysis of covariance was performed on the percentage of baseline smoking scores for the three treatment conditions during the posttest, 1st follow-up, and 2nd follow-up weeks. Again, the average daily number of cigarettes smoked during baseline served as the covariate. This analysis revealed no significant main effect or interactions involving booster as a factor. Accordingly, the booster factor was dropped, and a 4 (treatment) \times 3 (trials) analysis of covariance was performed on posttest, first follow-up, and second follow-up data, with the untreated control condition being added to the design. Significant main effects for treatments, $F(3, 55) = 6.59$, $p < .001$, and for trials, $F(3, 55) = 14.85$, $p < .001$, were found. Specific comparisons revealed that subjects in each of the three treatment conditions showed a significant return in the direction of baseline from the posttest to the subsequent follow-up weeks (all $ps < .005$). Subjects in the untreated control condition showed no change during this period ($F < 1$). At the time of the first follow-up session, subjects in the package condition were smoking less than subjects in the rapid-smoking ($p < .07$), nonspecific ($p < .05$), and untreated control conditions ($p < .005$). At the time of the second follow-up session, subjects in the package condition were still smoking less than those in the rapid-smoking ($p < .07$) or untreated control conditions ($p < .005$). Although the difference between the package condition and the nonspecific condition was 28.6%, this difference failed to attain significance. Nonetheless, at the time of both the first and the second follow-up sessions, the package condi-

tion was the only treatment condition that differed significantly from the untreated control condition.

In addition to the percentage of baseline smoking data, the proportions of completely abstinent subjects in each condition were examined. Chi-square analyses demonstrated significant differences in the proportion of abstainers in the various conditions at the posttest session, $\chi^2(3) = 11.1$, $p < .02$, and at the second follow-up session, $\chi^2(3) = 8.5$, $p < .04$. At posttest, the package condition contained a substantially larger proportion of abstainers (65%) than the control condition (0%, $p < .005$), the rapid-smoking (26%, $p < .02$), or the nonspecific condition (33%, $p < .06$). Similarly, at the time of the second follow-up, the package condition contained a larger proportion of abstainers (45%) than the control condition (0%, $p < .06$), the rapid-smoking condition (17%, $p < .06$), or the nonspecific condition (12%, $p < .03$). It is clear that most of the differences between conditions that occurred in the percentage of baseline smoking data can be accounted for in terms of the proportion of abstainers found in each of the conditions.

Attitudes Toward Smoking

A 3 (treatment) \times 3 (booster) \times 3 (trials) analysis of covariance was performed on the posttest, first follow-up, and second follow-up scores of the semantic differential scale, with the corresponding pretest scores serving as the covariate. This analysis failed to reveal any significant main effects or interactions involving booster sessions. Accordingly, the booster factor was dropped, the untreated control condition was added to the treatment factor, and a 4 (treatment) \times 3 (trials) analysis of covariance was performed on the scores from the semantic differential scale. This analysis revealed a significant main effect for treatment, $F(3, 55) = 12.06$, $p < .001$. Duncan pairwise comparisons revealed that the subjects in the package condition held significantly more negative attitudes toward cigarette smoking than subjects in all other conditions at the time of the posttest (all $ps < .001$), with no differences occurring

among the other three conditions. At the first follow-up session, subjects in the package condition continued to express more negative attitudes than subjects in the control condition ($p < .001$), the nonspecific condition ($p < .005$), or the rapid-smoking condition ($p < .07$). At the time of the second follow-up session, subjects in the package condition were still evaluating cigarette smoking somewhat more negatively than those in the control condition ($p < .005$), the nonspecific condition ($p < .08$), and the rapid-smoking condition ($p < .11$). All other comparisons failed to approach significance.

Discussion

Six months after treatment, the package treatment had produced a percentage of baseline smoking of 41% and an abstinence rate of 45%. These results are substantially better than figures reported for single treatment studies (McFall & Hammen, 1971) and also better than figures reported by Danaher (1977) in his package treatment study. These results are somewhat lower than those of other recent investigations using combinations of techniques (Best, 1975; Delahunt & Curran, 1976; Lando, 1977; Pederson et al., 1975). However, as indicated earlier, these latter studies suffered from several methodological weaknesses that may have inflated their results.

The present study contained a number of safeguards to improve on the validity of its findings. Experimenter bias was minimized by using tape-recorded treatment components and multiple therapists who were blind to the hypotheses of the study and the conditions being compared. In addition, a number of checks were used to help assure the accuracy of subjects' cigarette consumption data. Subjects were informed that they would receive lie detector tests, informants were used to confirm subjects' smoking status, and a disguised market survey was used at the end of the study.

The package condition also demonstrated highly favorable results when compared with the other conditions in the present study. After 6 months, the package treatment was the only condition with a percentage of base-

line smoking significantly lower than the untreated control condition. In addition, this percentage figure was 38% below that of the rapid-smoking condition and 29% below that of the nonspecific condition. Finally, the abstinence rate for the package condition at 6 months was substantially greater than the abstinence rate for each of the other conditions (all $ps < .06$).

Clearly, the package treatment demonstrated effectiveness beyond what could be attributed to nonspecific factors such as motivated volunteering, structure, self-monitoring, information, and encouragement. Borckovec (1973) has argued that placebo groups or nonspecific treatment groups seldom constitute adequate controls for expectancy, since the subjects in these groups rarely hold as favorable a set of expectancies as do those in the valid treatment groups. In the present study, however, an expectancy questionnaire was administered during the first treatment sessions, after subjects had heard descriptions of the treatments that they were about to receive. Subjects in all three treatment conditions held comparable initial expectancies, suggesting that differential expectancy at the start of treatment does not account for the differences between the package and the nonspecific conditions.

The present design did not permit the identification of the effects attributable to each of the component procedures within the package treatment. However, reports on a follow-up questionnaire by a number of the subjects indicated that cognitive restructuring and emotional role playing were particularly useful in aiding them in making the "real" decision to quit and that relaxation training and behavioral rehearsal were useful as coping strategies once that decision was reached. In contrast, the rapid-smoking component received almost no endorsement by subjects. In addition, the highly aversive nature of this procedure was clearly demonstrated. Six subjects actually vomited during rapid-smoking trials. Most other subjects reported extreme physical discomfort, including dizziness, headaches, sweating, and nausea, with effects lasting well over an hour after rapid-smoking trials.

In spite of its aversiveness, rapid smoking did not prove to be a very effective procedure. Subjects in the rapid-smoking condition achieved a percentage of baseline smoking of 73% and an abstinence rate of 17% after 6 months, figures that are almost identical to the results attained by McFall and Hammen (1971) using nonspecific treatment. Clearly, the results of our study stand in sharp contrast to those of Danaher (1977), both in terms of the effectiveness of our package treatment and the lack of effectiveness of rapid smoking. Further research is needed to explain these differences, but for the present, two points are noteworthy. First, the results obtained for our treatment package are much more comparable to those of other treatment packages (Best, 1975; Delahunt & Curran, 1976; Pederson et al., 1975) than is the case for Danaher's study. Second, other recent investigations (Lando, 1975, 1976; Sutherland et al., 1975) have begun to cast doubt on the effectiveness of rapid smoking.

The package treatment might be improved by strengthening the cognitive restructuring, emotional role-playing, relaxation, and behavioral rehearsal components and eliminating the rapid-smoking trials. It would also seem advisable to include more procedures aimed explicitly at teaching controlled smoking. Almost all of the success in the package condition was due to relatively large proportion of abstinent subjects in that condition. Little was accomplished by way of teaching nonabstinent subjects to smoke at reduced, medically safer levels. Controlled-smoking procedures addressed explicitly to those who are unwilling to quit might represent an improvement over the current package treatment. The issues regarding abstinence and controlled smoking are comparable to those currently being debated in the area of alcoholic treatment (e.g., Vogler, Compton, & Weissbach, 1975).

Finally, the results of the present study replicate those of Kopel (1974) in demonstrating the lack of effectiveness of booster sessions. In spite of several investigators' (e.g., Hunt & Matarazzo, 1973; Lando, 1975) remarks that booster sessions might

insure continued "immunization" among non-smokers while rescuing backsliders, the present study revealed no effects for booster sessions in terms of cigarette consumption or self-report measures of attitudes toward smoking. In considering these results, it should be noted that the booster sessions in the current study did not represent complete replications of the original treatments that may have attenuated their potential effectiveness.

Geriatric Patients Who Improve in Token Economy and General Milieu Treatment Programs: A Multivariate Analysis

Brian L. Mishara

University of Massachusetts at Boston

Chronic geriatric mental hospital patients were randomly assigned to token economy and general milieu programs. In each program, staff received the same amount of training, and the physical environments were identical. Results showed significant decreases over 6 months on both wards in frequency of bizarre and unusual behaviors. Incontinence decreased immediately after transfer to the treatment wards, and there were changes over 6 months in the amount of staff care given to patients. Multiple discriminant analyses indicated that in each ward different constellations of pretreatment characteristics discriminated between patients who improved and those who did not improve in the frequency of bizarre and unusual behaviors. In the token economy, improved patients can be characterized as less "institutionalized," in better physical condition, and actively exhibiting their troubles. In the general milieu, improved patients can be discriminated by less responsiveness to an interviewer. Results are interpreted in view of the different characteristics of each program.

Most research on the rehabilitation of chronic elderly mental hospital patients has focused on finding and evaluating one potentially useful treatment method rather than comparing techniques or trying to determine which elders benefit from which intervention programs. Two promising intervention techniques, token economy and general milieu programs, have been shown to be effective, but not all clients improve under treatment. This poses a dilemma for the practitioner who must choose an appropriate intervention method for particular clients. Often the

choice is made on the basis of ideological preferences rather than empirical data regarding which client characteristics relate to improvement under each condition. This article offers preliminary indications based on multiple discriminant analyses of which pretreatment client characteristics discriminate between those who improved and those who did not improve in a token economy and a general milieu treatment program.

There have been few attempts to discriminate between geriatric clients who improve under treatment and those who do not. Kleban, Lawton, Brody, and Moss (1976) used multivariate techniques to determine which characteristics of their subjects best predicted improvement in either an individually planned treatment program or a standardized treatment procedure. Their results indicated that age was the single most consistent predictor of success in both groups, with the younger subjects more likely to improve. Those who improved most in the individualized program tended to be more self-sufficient and active, with the social skills necessary to profit from their individualized contact with staff.

This study was conducted at Northville State Hospital, Northville, Michigan. It is based in part on a paper presented at the annual meeting of the American Psychological Association, San Francisco, August 1977.

The author wishes to thank Barbara Robertson, John Moir, and the other Northville staff whose involvement in the implementation of these programs was essential. Also, thanks are due to Derek Hybels and John Murphy for help in data analysis and A. Harvey Baker, Larry Gaines, and Robert Kastenbaum for their comments on earlier drafts of this article.

Requests for reprints should be sent to Brian L. Mishara, Department of Psychology, University of Massachusetts, Boston, Massachusetts 02125.

Sherwood, Morris, and Barnhart (1975) used the results of a discriminant function analysis to develop a system for assigning elderly people to appropriate residential settings. Their system was designed to differentiate elders who need the greater care offered by institutionalization from those who require less supervised settings or who can live independently or semi-independently. After further study and cross-validations, their approach may prove useful in deciding who should be institutionalized and who would be better off living independently.

The Sherwood et al. (1975) and Kleban et al. (1976) studies assessed characteristics of people who would benefit from more or less individual care. The present study is based on treatment conditions in which the amount of individual care was designed to be equivalent under both conditions. The major difference between the programs was their derivations from quite different theoretical perspectives. The token economy program, in the behaviorist tradition, involved careful application of operant reinforcement principles. On the other hand, the general milieu program provided the same reinforcements freely in the tradition of humanistic psychology and current research in environmental psychology.

Milieu treatment methods have recently gained attention for their potential to rehabilitate long-term institutionalized geriatric patients (e.g., Bok, 1971; Gottesman, 1973; Gottesman, Quarterman, & Cohn, 1973). Their findings have been generally accepted—An improved milieu is more conducive to positive therapeutic change than impoverished custodial care settings. Although these findings seem almost self-evident, findings from research on milieu treatment provided the impetus for practitioners to rehabilitate many chronic geriatric mental patients who were previously denied treatment, because it was thought that treatment attempts would be a waste of time.

Token economy programs that utilize operant conditioning principles have been quite successful with chronic mental patients (e.g., Ayllon & Azrin, 1968; Ayllon & Michel, 1959; Krasner, 1971). A number of

the token economy studies included elderly subjects (Atthowe & Krasner, 1968; Lee, 1969; Mueller & Atlas, 1972). Although token economies for just the elderly have been rare, behavior modification techniques have been increasingly accepted as a useful method for geriatric intervention (see Hoyer, Mishara, & Riedel, 1975).

In general, available data suggest that token economy programs are better than control situations in which no treatment is given (Gripp & Magaro, 1971; Maley, Feldman, & Ruskin, 1973; Shean & Zeidberg, 1971). Greenberg, Scott, Pisa, and Friesen (1975) found that a milieu treatment program combined with token economy was more effective than a token economy alone. However, the review by Gripp and Margaro (1974) suggested that it is still unclear which variables affected the outcome of token economy programs.

In this study discriminant function analysis was chosen, since the discrimination made parallels the real-life decisions faced in rehabilitation settings. With the development of different kinds of treatment for geriatric patients, hospital staff are faced with the problem of choosing between the various rehabilitation approaches that are currently available. The discriminant function approach may help to identify variables that may affect the outcome of such choices. Also, because of their diagnoses as suffering from incurable degenerative brain disease, it is frequently expected that no such patients would benefit from rehabilitation efforts. Their medical prognosis was continued decline. Given this expectation, *any* improvement sustained over 6 months could be an important indication of rehabilitation potential, hence the choice of two discrete populations, the "improved" and "unimproved." It was decided a priori that since these were mental hospital patients, the main indication of improvement would be decreases in the frequency of bizarre and unusual behaviors. Secondary measures of improvement were reduced frequencies of incontinence, increased interpersonal communication, and reduced staff care given for personal hygiene and self-care.

^e Per hour.

Method

Subjects

Eighty elderly people (40 men and 40 women) were selected randomly from the "medical" unit of a large state mental hospital to populate two new coed treatment wards, each with 20 males and 20 females. These people were on the medical unit because of their diagnoses of suffering from incurable chronic brain syndromes presumably associated with old age. Approximately half of the subjects were selected from those people who gave evidence of ability to communicate with others verbally. At the time of the original selection, only 31 subjects were communicative. Half of the communicative subjects were randomly assigned to each ward, and the remaining subjects were randomly divided between the wards.

The mean age was 68.8 years ($SD = 5.1$ years). The mean length of current hospitalization was 21.4 years ($SD = 14.7$ years). Most of the participants were previously involved in active rehabilitation programs on other units. These patients were the "failures." After failing to meet criteria of rehabilitation set up by these programs, people were transferred to the medical unit.

On the medical unit, only custodial care was available. A medical doctor made daily rounds, but there was no psychosocial treatment available—there were no psychologists, psychiatrists, or social workers involved actively in their treatment. The patients mostly wore hospital gowns in place of regular clothing, few ever left the wards, and the only available recreation was television.

Procedure

Identical numbers of nursing staff with equivalent training were assigned to each program. Nursing staff on all three shifts on each ward first participated in 13 weeks of training meetings for 3–4 hours a week. Training included discussions of how it feels to work with chronic elderly patients, demonstrations of how it feels to be disabled, and what it is like to work in a custodial hospital ward. The staff was instructed that the programs would involve (a) more activities and social stimulation, including better foods, radio-phonographs, social events, environmental decorations, better clothes, and so forth; (b) increased opportunity for patients to choose how to run their daily lives; and (c) more awareness of staff for whose benefit they were doing things: to satisfy their own needs or the needs of the patients.

During the last 7 weeks of the training period, staff on the general milieu ward participated in open-ended discussion, whereas staff on the token ward learned the operant conditioning procedures and theory involved in a token economy program.

Basically, the token economy program was modeled after that designed by Ayllon and Azrin (1968). Individuals were rewarded for desirable behaviors including social interaction with other patients, ward work, personal hygiene, and self-care activities. Table 1 lists some of the ways tokens could be earned. A detailed but simple bookkeeping system was used to keep track of all tokens given out and taken in, and the midnight shift audited the daily tallies and reported any discrepancies. Tokens could be exchanged for secondary reinforcements such as cigarettes, wine, permission to leave the ward, extra food, and other supplements. The staff met regularly to revise the token system and determine which behaviors should be rewarded.

The same secondary reinforcements that could be purchased by the token economy ward were available free to anyone on the general milieu ward who wanted them. Staff were instructed to increase environmental opportunities without any systematic reinforcement of behaviors. For example, in the

general milieu ward, food supplements such as coffee, wine, ice cream, and sandwiches were available free on a daily basis to anyone who wanted them. Whereas on the token economy ward these same foods were sold for tokens. On the general milieu ward, activities such as making handicrafts were available to anyone who wanted to participate, but on the token economy ward patients were paid by the hour for their work on these projects.

The physical environments on both wards were identical. The wards had duplicate floor plans and duplicate furniture at the start of the programs. On both wards efforts were made to acquire decorations and some more comfortable furniture, though the environments could still be regarded as quite "institutional" in character.

Prediction Measures

Before being transferred to the new research wards, data on all participants were gathered on the following measures, which were later entered into the discriminant analyses as the independent variables:

Psychotic Inpatient Profile. All participants were observed for 3 days by nursing staff using Lorr's Psychotic Inpatient Profile (PIP; Lorr & Vestre, 1969).

VIRO (Vigor Intactness Relationship Orientation). Research assistants rated subjects' interpersonal behavior using the VIRO scale developed for use with geriatric patients by Kastenbaum and Sherwood (1972). The VIRO scale consists of three scores: Presentation (based on the initial interpersonal behavior toward the interviewer), Interaction (based on interpersonal behavior during $\frac{1}{2}$ hour, and Orientation (which assesses orientation as to time, place, and person).

Staff evaluations of patient abilities. Staff who were familiar with the patients filled out questionnaires concerning observed dressing abilities and habits, personal hygiene level, physical condition (difficulties and illnesses), and behavioral disabilities.

Prediction Measure Reliabilities

As a check of the reliability of the PIP observations, on 10 occasions a research assistant spent 3 days observing on the ward in the course of other activities and filled out profiles on participants who were being observed by staff. There were few disagreements between ratings by staff and observers, and what little there was reflected a seemingly random pattern of errors of omission on the part of staff. To test the reliability of the VIRO, 20 elderly patients were interviewed twice within 2 weeks by different research assistants. The correlations between the two interviewers on the sections of VIRO were .94, .98, and .99.

Treatment Outcome Measures

The treatment outcome measures were based on 1-day observations by nursing staff, who recorded

the frequencies of occurrence of specific target behaviors. Observations were conducted in a random sequence, so that for 1 day every 2 weeks each patient was observed by a randomly assigned staff member on both the day and afternoon shifts. Staff conducted the observations during the course of their usual daily activities. Observations were from the month before the patients were transferred to research wards until 6 mo. after the programs began.

The main outcome measure was the frequency of bizarre and unusual behaviors. The behaviors included in this variable were defined on an individual basis after extensive observations. Typical types of behaviors included confused verbalizations (e.g., "My mother is coming today to take me to the zoo."), conversations or reports of conversations with people not actually present (e.g., "Jesus Christ just told me to throw peas on the ceiling."), self-injurious behaviors (e.g., scratching one's arm until it bleeds), unusual movements (e.g., "sweeping" the floor without a broom), and so forth. Secondary outcome measures were the frequency of occurrence of incontinence, the frequency of conversations with other patients, and the number of times nursing staff gave care or help in personal hygiene and patient self-care activities.

Treatment Outcome Measure Reliabilities

As a check of the reliability of these staff observations, outside experimenters occasionally spent 1 day on the ward observing the same behaviors in specific patients. Disagreements between staff and observer ratings were few, and they seemed to follow a random pattern. As a second check on the rating reliabilities, identical independent observations were conducted on the same day for the same patients by members of the day and afternoon shifts and were compared. As was expected, the day shift staff, who spent more waking-time contact with patients in general, reported more behaviors. The Spearman rank-order correlations (ρ) between observations on the two shifts ranged from .71 to .92 ($n = 37$ in the general milieu program, and $n = 36$ in the token economy), with the median correlation being .77. (All correlations were significant at $p < .01$.)

Statistical Analyses

General improvement according to staff observations was analyzed by sign tests on changes from before treatment to the end of 6 months on the rehabilitation wards. (See Siegel, 1956, pp. 68-75.) Sign tests were chosen for the primary analysis, since the data were not interval data.

For the multiple discriminant analyses, patients were classified as either having improved or as not having improved from before the start of the treatment program until 6 months after being transferred to the new treatment units. For each separate program a stepwise linear discriminant analysis was performed using the nine PIP scales, the three VIRO scales, the four staff evaluations of areas of patient ability, and age, sex, and total years of hospitalization

to determine which of these factors discriminated between the population of individuals who improved and those who did not improve. Supplementary multiple regression analyses were performed in order to gain an indication of the amount of variance accounted for by the measures.

Results

The first issue is whether or not either or both of the treatment programs had an effect on the primary target variable or any of the three secondary outcome measures. Given that these patients had a prognosis of further deterioration, it is not surprising that the majority showed no change from before the start of the programs to 6 months after the programs began. Most patients who changed decreased the frequency of bizarre and unusual behaviors (see Table 2). These improvements occurred in both the token economy (sign test, $p = .059$) and the general milieu (sign test, $p = .003$) programs, showing treatment effects.

Regarding the secondary outcome measures (see Table 2), there were significant improve-

ments on frequency of incontinence in the general milieu program (sign test, $p < .001$) and improvements in the token economy programs (sign test, $p = .062$). Care given by nursing staff was significantly reduced after 6 months only on the token economy ward (sign test, $p < .001$), and there was no significant improvement on frequencies of conversations with other patients on either ward.

Inspection of the data indicated that the declines in frequency of incontinence occurred entirely between the pretest and the first observation immediately after transfer to the two treatment units. Although these improvements were sustained over the 6-month treatment, no further improvement occurred later on. Data on frequency of care given by nursing staff indicated that there was an immediate significant decrease in care given in the general milieu program immediately after the programs began (sign test, $p < .022$), followed by a gradual increase over 6 months to the pretest levels.

Table 3 summarizes the stepwise linear discriminant analyses for the populations of

Table 2

Sex			.45385	2 (.5835)
Staff evaluations				
Dressing habits and abilities	.46640	6 (.3290)		
Physical condition	-.38735	4 (.4653)	9.86923	1 (.6597)
VIRO interaction				
Age				
Total years of hospitalization	4.09605	3 (.5601)		
PIP				
Anxious depression	-2.50197	5 (.4055)		
Care needed	.98419	2 (.6979)		
Psychotic disorganization	-8.16205	1 (.7960)		

Note. Linear discriminant coefficients appear in parentheses. VIRO = Vigor Intactness Relationship Orientation.

people who improved and did not improve on frequency of bizarre and unusual behaviors. The order of entry column indicates the rank order of the ability of the variables to distinguish between the two groups of patients when factors already entered in the discriminant function are controlled. Table 4 shows the results of multiple regression analyses on the same data, in which the order of entry of variables was the same as for the linear dis-

criminant analyses. Since the regression analyses were included in order to assess the amount of variance accounted for by each variable, the table shows the multiple correlations at each step, R^2 (amount of variance accounted for) at each step, and the simple correlation for each variable. Table 5 indicates the frequencies and percentages of misclassifications that would occur in these samples if the discriminant function were used to assign individuals to the improved or unimproved groups.

Table 4
Summary of Results from Multiple Regression Analysis With Order of Entry in Equation the Same as for the Discriminant Analyses

Variable	R	R^2	Simple r
Token economy program			
Psychotic disorganization	.199	.040	-.199
Care needed	.428	.183	.227
Total years hospitalization	.558	.312	.151
Physical condition	.609	.371	-.079
Anxious depression	.639	.408	-.163
Dressing habits	.646	.417	-.085
General milieu program			
VIRO interaction	.430	.184	.430
Sex	.632	.399	.554

Note. VIRO = Vigor Intactness Relationship Orientation.

In the general milieu program, populations that did and did not improve in bizarre and unusual behaviors could be discriminated best by the VIRO interaction score, followed by sex. Improved patients were generally less responsive on VIRO interaction ratings, and they tended more often to be males. On the token economy ward, PIP psychotic disorganization best discriminated between improved and unimproved patients, followed by PIP care needed, length of total hospitalization, staff evaluation of physical condition, PIP anxious depression, and staff evaluations of dressing habits. The improved patients generally had greater PIP psychotic disorganization, less PIP care needed, less total hospitalization, better staff ratings of physical condition, more anxious depression, and worse dressing habits.

Table 5
*Numbers of Cases Misclassified in Groups
 by the Stepwise Discriminant Analyses*

Group	Program	
	Token economy	General milieu
Improved as unimproved	1/11 (9.1)	4/11 (36.4)
Unimproved as improved	1/12 (4.3)	3/25 (12.0)
Total	2/34 (5.9)	7/36 (19.4)

Note. Numbers in parentheses are percentages.

Discussion

The token economy and general milieu programs were both successful in bringing about positive behavioral changes in a number of these chronic elderly mental hospital patients with organic diagnoses. Given the expectation that due to their diagnoses of irreversible chronic organic brain damage they should not be likely to improve, it is not unusual that the majority showed no change on the main outcome measure, frequency of bizarre and unusual behaviors. Most people showed no change, though significantly more people improved than declined. Still, the proportion of people who did improve (almost one third) supports current research in clinical gerontology, which indicates that many chronic elderly patients who were previously considered hopeless have rehabilitative potential. These findings are bolstered by the significant numbers who decreased in the frequency of incontinence, which had been considered by many staff members as a purely medical degenerative condition.

The lack of significant numbers of people increasing in their frequency of conversations with other patients is interesting. On both wards, although many conversed more frequently, almost equal numbers had less frequent conversations. I would like to believe that those who increased their conversations developed friendships and those who decreased their conversations stopped engaging in arguments or other undesirable behaviors. However, no data are available to explain this lack of findings, so one must assume that any

changes on this dimension are due to chance.

It is also of interest that care given by nursing staff for personal hygiene and self-care declined in the token economy program, but it declined at the start of the general milieu programs only to gradually increase to the pretreatment level. In the token economy it was obvious that the decline in staff care was a direct result of reinforcing patient behaviors, which lessened the need for staff help. In fact, nursing staff seemed particularly careful to reward behaviors that made their job easier. Many staff meetings were spent modifying the program so that other therapeutic behaviors would be the primary targets.

In the general milieu program, patients did more for themselves, which resulted in the initial drop in staff care. They required less help in basic care such as putting on one's clothes or taking a shower. However, as the program progressed, patients began to increase their demands on staff for additional forms of care and new services that were not given before. They demanded more meticulous grooming, such as careful hairstyling. In this instance the outcome variable that was defined a priori changed its meaning as the program progressed.

One possible explanation of these results is that the improvements were unrelated to the treatment methods—that resulted simply from a general "Hawthorne" effect of putting staff effort into patient care. If this explanation were correct, the results would indicate that any treatment is effective for this population when compared to no treatment at all. Clearly, this seems to be the case with regard to the decreases in the incidence of incontinence. These improvements occurred immediately on transfer to the new treatment environments but before the activities in the treatment programs had an opportunity to get under way.

An alternative hypothesis is that different types of patients are more likely to respond to each of the two programs. Support for this latter hypothesis can be seen in the results from the multiple discriminant analyses. Patients who improved in the token economy program could best be discriminated by their active psychotic disorganized behaviors, less

need for staff care, more recent admission to a mental hospital, better physical condition, active discontent, and sloppy dressing habits. This constellation of variables generally indicates the less "institutionalized" patients who are in better physical conditions and actively exhibit their troubles. However, in the general milieu program, patients who improved could be best discriminated on the basis of their lesser responsiveness to an interviewer.

These characterizations seem reasonable in view of the demands of each program. The token economy required patients to be sufficiently alert and motivated to engage in target behaviors that would result in reinforcement. Generally, more active involvement was necessary. However, the general milieu program did not demand active involvement, it only provided an enriched environment that was more supportive to individual needs.

One additional observation may be particularly relevant in deciding which type of program to conduct: Staff in the token economy program often reported that they were succeeding in their efforts, whereas staff in the general milieu program more often reported that they felt that they were getting nowhere. The reports of dismay in the milieu program occurred even when progress was being made. This difference in staff reactions may reflect the token economy staff's greater comfort with the highly structured token system. In the token economy, staff behaviors were clearly specified in most situations, and daily feedback was provided by charting of reinforcement frequencies for each patient. In the general milieu program, staff had to rely more on their intuition about how to behave. They were not given daily tallies that could provide feedback about the effectiveness of their actions.

Overall, this study suggests that different patient characteristics may discriminate between those who improve and those who do not in different types of rehabilitation programs. Further research in this area, and particularly cross-validations of these findings, may help clarify which patients benefit from which types of treatment. Perhaps further research will allow hospitals to rehabilitate a greater proportion of their patients by offering

alternative programs to meet the special needs of different patient populations.

Veridicality of Self-Report: Replicated Correlates of the Wiggins MMPI Content Scales

David Lachar and Richard S. Alexander
Lafayette Clinic, Detroit, Michigan, and Wayne State University

Correlates of the 13 Minnesota Multiphasic Personality Inventory Wiggins content scales were identified using both single-sample and cross-validation paradigms in a sample of 384 male clients who received a mental health evaluation at a military medical facility. Characteristics of both high-scoring and low-scoring clients were obtained for each scale, and interpretations of high scale elevations are proposed that reflected scale content, psychometric properties, and correlate characteristics. The 48 replicated and 28 single-sample correlates descriptive of high scorers significant at .01 reflected either the substantive nature of each scale or suggested primary characteristics expected of high scorers on each scale, whereas the additional 69 single-sample correlates significant at .05 often provided the descriptions needed to "round out" each scale interpretation. Evaluation of the correlates of low scorers essentially supported the position that low scores reflect the absence of descriptors characteristic of high elevations on the same scale. A factor analysis of the content, clinical profile, A, and R scales supported the interpretive intent of the content scales, as well as suggested their relative vulnerability to a defensive response set.

The 13 content scales of the Minnesota Multiphasic Personality Inventory (MMPI) were constructed by Wiggins (1966) to study the relation between item content and scale validity. They were developed by applying both psychometric and intuitive procedures to the original content classifications of Hathaway and McKinley (1951). Each scale item was assigned exclusively to its respective scale only if it obtained a point-biserial correlation with the total scale score in excess of .30, which also exceeded its correlation with the remaining content scales.

Initial study of the content scales revealed meaningful differences between various normal and psychiatric samples and between samples defined by traditional diagnostic classifications (e.g., schizophrenic psychoses, brain disorders, etc.). The factor structure of the scales was also supportive of their interpretive intent

(Wiggins, 1969). Additional construct validity has been demonstrated in a study that related content scale elevation to clinical profile code-type correlates (Payne & Wiggins, 1972), in studies that compared scale scores of groups differing in composition (Cohler, Grunebaum, Weiss, Hartman, & Gallant, 1975; Jarnecke & Chambers, 1977; Mezzich, Damarin, & Erickson, 1974; O'Neil, Teague, Lushene, & Davenport, 1975), as well as in studies that correlated content scale scores with other MMPI scales and other personality measures (Derogatis, Rickels, & Rock, 1976; Hoffmann & Jackson, 1976; Taylor, Ptacek, Carithers, Griffin, & Coyne, 1972; Wiggins, Goldberg, & Appelbaum, 1971).

Wiggins (1966) suggested that the content scales may serve as a supplementary source of information to interpretations derived from the empirically keyed MMPI profile scales. The content scales were constructed to measure the substance of the client's communication that is directed at the examiner. The interpretation of these scales represents a view of test response midway between the naive-rational and the radical-empirical perspec-

tives (Dahlstrom, 1969). Suggested interpretations of the content scales (Wiggins, 1966) reflect this interpretive intent by emphasizing that scale elevations reflect *admission* of various symptom clusters.

The present study seeks to evaluate the extent of agreement between self-report and clinical impression among clients by investigation of the external correlates of the Wiggins content scales. The study design and character of these scales also allows an examination of the relation between method of correlate selection and degree of conceptual fit with manifest scale content. A final goal of this investigation is the construction of interpretive statements for each scale to describe high-scoring clients.

Method

Subjects

The 384 male subjects were United States Air Force personnel and their dependents who had received a psychiatric evaluation between July 1972 and March 1973 at Wilford Hall Medical Center, Lackland Air Force Base, San Antonio, Texas. Mean age of this sample was 26.3 years (range = 18-57), and 95.4% were under 24 years of age. The mean educational level was 12.5 years, with 24% having more than a high school education. Marital status was about evenly divided between single (49%) and married (45%), and 6% were either divorced or widowed. These subjects were seen by different diagnostic components of the Department of Mental Health: 35% were inpatients on a psychiatric service, 18% were inpatients on general medical or neurology/neurosurgery services, 39% were seen at the outpatient clinic, and the remaining 8% were evaluated by the mental hygiene clinic during participation in basic training.

Measures

Each subject completed the standard booklet form of the MMPI as a routine part of his evaluation. These MMPIs were obtained as part of a previously reported study of rated accuracy of an automated interpretation system for the clinical profile scales (Lachar, 1974). *T* scores for the content scales were obtained using norms reported by Wiggins et al. (1971), and raw scores for profile scales and Scales *A* and *R* (Welsh, 1956) were converted to *T* scores using the Hathaway and Briggs (1957) norms.

Adjective correlates were collected from the clinician who had evaluated each subject using a mental health evaluation form, which was completed when the MMPI was administered. In addition to various identification, demographic, and clinical data, this

evaluation form permitted the description of each client by checking 81 possible descriptive adjectives. These adjectives were subjectively placed under the headings affect ($n = 18$), interpersonal relations ($n = 10$), motor behavior ($n = 9$), psychological efficiency ($n = 4$), patient-therapist relationship ($n = 3$), history ($n = 7$), thought process ($n = 8$), thought content ($n = 7$), and physical complaints ($n = 15$). Since many of the physical complaint descriptors were selected infrequently, these 15 adjectives were also collapsed into a composite variable labeled *physical complaint present*.

Procedure

MMPI protocols of dubious validity ($F > 25$ raw score) or substantial missing data ($Q > 30$ raw score) were omitted from this analysis, reducing the study sample by 21 subjects to 363. All subjects were then designated as either high scorers, low scorers, or "other" for each of the 13 content scales. Though score distributions allowed designation of $T < 41$ as the criterion inclusion rule for low scorers, the initial criterion inclusion rule of $T > 69$ for high scorers was modified to $T > 59$ for the Manifest Hostility, Authority Conflict, Feminine Interests, Hypomania, and Religious Fundamentalism scales to form sufficiently large criterion groups for these scales.

Correlates were selected for the total sample (criterion group vs. all remaining protocols) using the chi-square statistic at the .05 and .01 levels. In addition, each criterion group and the remaining sample were randomly split, and the adjective correlates significant at least at the .10 level in both samples were designated as replicated, with a resultant joint probability of at least .01.

To assist in definition of the construct dimensions related to each content scale, *T* values for the clinical profile scales, *A*, *R*, and the 13 content scales were intercorrelated. This correlation matrix was then submitted to a principal components factor analysis, and the resulting factor matrix was rotated to a varimax criterion.

Results

Criterion sample size, correlates replicated at .01, and correlates not replicated but significant at .01 or .05 for the total sample are presented below.¹ Forty-eight correlates replicated for high-elevation criterion groups, whereas only 18 correlates cross-validated in the analysis of low-score criterion groups. Approximately twice the number of correlates

¹ Adjective base rates and criterion group frequencies for significant correlates and scale intercorrelations are available on request from the first author.

were obtained by these three selection methods for the criterion groups defined by high elevations than for criterion groups defined by low elevations (145 vs. 88).

Organic Symptoms (ORG)

$T > 69$ ($n = 79$). Replicated at .01: impotent/decreased libido, fatigue, insomnia, poor memory, anorexia, headache, joint pains. Single sample significant at .01: depressed, difficulty in concentration, paucity of ideation, back pain, loss of consciousness, physical complaint present. Single sample significant at .05: less hyperactive/hypomanic, chest pain.

$T < 41$ ($n = 24$). Replicated at .01: less depressed. Single sample significant at .05: shallow affect, talkative, less fatigue.

Poor Health (HEA)

$T > 69$ ($n = 56$). Replicated at .01: chest pain. Single sample significant at .01: anorexia, diarrhea, shortness of breath. Single sample significant at .05: worrisome, constipation.

$T < 41$ ($n = 19$). Replicated at .01: less depressed, shallow affect. Single sample significant at .05: less anxious, less worrisome, less withdrawn.

Depression (DEP)

$T > 69$ ($n = 87$). Replicated at .01: impotent/decreased libido, retarded (motor), sense of inadequacy/inferiority. Single sample significant at .01: depressed, withdrawn. Single sample significant at .05: guilty, less inappropriate affect, combative when intoxicated, paucity of ideation.

$T < 41$ ($n = 32$). Replicated at .01: less depressed, less withdrawn, less sense of inadequacy/inferiority. Single sample significant at .05: less anxious, less guilty, less worrisome, talkative, less insomnia, less financial problems, less ideas of reference, physical complaint present.

Poor Morale (MOR)

$T > 69$ ($n = 65$). Replicated at .01: depressed, combative when intoxicated, paucity

of ideation, sense of inadequacy/inferiority, anorexia. Single sample significant at .01: fearful/phobic, tremulous. Single sample significant at .05: guilty, less inappropriate affect, less labile, suspicious, tearful, withdrawn, retarded (motor), insomnia, less religiosity.

$T < 41$ ($n = 64$). Replicated at .01: less depressed, less fearful/phobic. Single sample significant at .01: less sense of inadequacy/inferiority. Single sample significant at .05: less anxious, less guilty, less fearful, less worrisome, less impotent/decreased libido, less withdrawn, less agitated/restless, less indecisive, less difficulty in concentration, less insomnia, defensive, less ideas of reference, nausea/vomiting.

Social Maladjustment (SOC)

$T > 69$ ($n = 62$). Replicated at .01: apathetic, depressed, fearful/phobic, worrisome, withdrawn, compulsive, retarded (motor), sense of inadequacy/inferiority, suicidal thoughts. Single sample significant at .01: guilty, insomnia. Single sample significant at .05: fatigue, less poor judgment, constipation.

$T < 41$ ($n = 69$). Replicated at .01: less depressed, less fearful/phobic, less perplexed, less withdrawn. Single sample significant at .01: less poor memory, malingering. Single sample significant at .05: less apathetic, less guilty, less suspicious, less tearful, less worrisome, amoral, less dependent, less passive, less indecisive, less retarded (motor), less difficulty in concentration, less confused, less sense of inadequacy/inferiority, less suicidal thoughts, headaches.

Manifest Hostility (HOS)

$T > 59$ ($n = 24$). Replicated at .01: hostile, less suspicious, assaultive. Single sample significant at .01: chest pain. Single sample significant at .05: moody, amoral, impulsive, combative when intoxicated.

$T < 41$ ($n = 48$). Single sample significant at .05: less depressed, less moody, less impotent/decreased libido, less agitated/restless, less insomnia, less ideas of reference, less sense of inadequacy/inferiority.

Family Problems (FAM)

$T > 69$ ($n = 86$). Replicated at .01: assaultive, impotent/decreased libido, insomnia, drug usage, marital conflict. Single sample significant at .01: agitated/restless, impulsive. Single sample significant at .05: excitable, less passive, combative when intoxicated, sense of inadequacy/inferiority, unrealistic feelings, less loss of consciousness.

$T < 41$ ($n = 34$). Replicated at .01: less depressed, homicidal, less marital conflict. Single sample significant at .01: abdominal pain. Single sample significant at .05: inappropriate affect, less sense of inadequacy/inferiority.

Authority Conflict (AUT)

$T > 59$ ($n = 94$). Replicated at .01: malingering. Single sample significant at .01: marital conflict, less autistic thought, less perfectionistic. Single sample significant at .05: assaultive, less withdrawn, destructive gestures, combative when intoxicated.

$T < 41$ ($n = 49$). Single sample significant at .01: less immature. Single sample significant at .05: less moody.

Feminine Interests (FEM)

$T > 59$ ($n = 75$). Replicated at .01: perplexed, difficulty in concentration, unrealistic feelings. Single sample significant at .01: suicide attempts, religiosity. Single sample significant at .05: homosexual, less impulsive, indecisive, insomnia, less malingering, less combative when intoxicated, confused, delusions, hallucinations.

$T < 41$ ($n = 39$). Single sample significant at .05: agitated/restless, malingering.

Phobias (PHO)

$T > 69$ ($n = 47$). Replicated at .01: fearful/phobic, worrisome, retarded (motor), anorexia. Single sample significant at .01: depressed. Single sample significant at .05: anxious, withdrawn, tremulous, poor memory, paucity of ideation, chest pain, joint pains.

$T < 41$ ($n = 42$). Single sample significant at .01: physical complaint present. Single

sample significant at .05: abdominal pain, back pain, visual problems.

Psychoticism (PSY)

$T > 69$ ($n = 54$). Replicated at .01: retarded (motor), autistic thought, paucity of ideation. Single sample significant at .01: anorexia. Single sample significant at .05: perplexed, suspicious, worrisome, less dependent, impotent/decreased libido, disorganized thought, incoherent, less perfectionistic, hallucinations, ideas of reference.

$T < 41$ ($n = 21$). Single sample significant at .05: less suspicious, less insomnia.

Hypomania (HYP)

$T > 59$ ($n = 104$). Replicated at .01: excitable, immature, hyperactive/hypomanic. Single sample significant at .01: agitated/restless. Single sample significant at .05: less compulsive, destructive gestures, less retarded (motor), malingering, less suicidal thoughts.

$T < 41$ ($n = 28$). Single sample significant at .01: less immature. Single sample significant at .05: nausea/vomiting.

Religious Fundamentalism (REL)

$T > 59$ ($n = 40$). Replicated at .01: less alcohol excess. Single sample significant at .01: delusions, religiosity. Single sample significant at .05: less impulsive, less drug usage, less marital conflict, autistic.

$T < 41$ ($n = 84$). Replicated at .01: homicidal, impulsive, drug usage. Single sample significant at .05: less moody, destructive gestures, confused.

The results of the factor analysis are presented in Table 1. Five factors were obtained that accounted for 96% of the common variance among these 28 scales. The first factor accounted for 57.2% of the variance and reflected somatic complaints (ORG, HEA, H_s , H_y) and a secondary emphasis of psychological discomfort (D , Pt , Sc). The second factor accounted for 16.3% of the variance and appeared to be organized around informant response style. Measures of symptom denial (L , K , R) characterized one end of this dimension, whereas the other was defined by ad-

Note. ORG = Organic Symptoms; HEA = Poor Health; DEP = Depression; MOR = Poor Morale; SOC = Social Maladjustment; HOS = Manifest Hostility; FAM = Family Problems; AUT = Authority Conflict; FEM = Feminine Interests; PHO = Phobias; PSY = Psychoticism; HYP = Hypomania; REL = Religious Fundamentalism.

*Factor loadings less than .40 have been omitted.

mission of pathology (*F*, *A*). Although only 1 of the 10 clinical profile scales loaded on Factor 2, 7 of the content scales obtained such loadings. The especially high and primary loadings of scales HOS, AUT, PSY, and HYP on Factor 2 suggested their susceptibility to a defensive response set. The third factor accounted for 11.1% of the variance and clearly represented a dimension characterized by depression (DEP, *D*), anxiety (PHO, *Pt*, *A*), and social withdrawal and alienation (SOC, *Si*, *Sc*). The fourth factor accounted for 7% of the variance and uniquely represented traditional sex role interest pattern (FEM, *Mf*). The final factor represented 4.4% of the vari-

ance and was characterized by Scales FAM, *F*, *Pd*, *Pa*, *Pt*, and *Sc*. This factor appeared to reflect both poor interpersonal relationships and the causal and resultant traits associated with interpersonal conflict.

Proposed interpretations of high content scale scores are presented in the appendix. These interpretations reflect a combination of scale item content, empirically supported scale correlates, and their frequency, as well as scale intercorrelations.

Discussion

The correlates obtained for the Wiggins content scales demonstrated substantial agree-

ment between client self-report and clinician evaluation. Evaluation of correlates of high scale elevations by method of correlate selection suggested that both the 48 replicated and 28 nonreplicated correlates selected at .01 directly reflected either the substantive nature of their corresponding content scale or primary characteristics expected of clients who score highly on each scale. This substantive agreement raises doubts as to the frequently stated need for the cross-validation of correlates (Boerger, Graham, & Lilly, 1974; Gynther, Altman, & Sletten, 1973; Lewandowski & Graham, 1972; Marks, Seeman, & Haller, 1974) if the level of significance for correlate selection is sufficiently conservative in analysis of sufficiently large samples. Inspection of the additional 69 correlates selected for the total sample at .05 reveals that they often provide the descriptors needed to "round out" each scale interpretation. The correlates of HOS ($T > 59$), for example, include "hostile, less suspicious, assaultive, chest pain" at .01, whereas inclusion of .05 descriptors adds "moody, amoral, impulsive, and combative when intoxicated."

Evaluation of the 25 correlates selected at .01 and the 69 correlates selected at .05 for low-elevation criterion samples supports the position that low scores reflect the absence of descriptors characteristic of high elevations on the same scale. This analysis does not exclude the possibility that some of the content scales reflect bipolar dimensions, as the potential correlate pool for this study did not include any favorably worded descriptors. An artifact of this analysis appears to be several physical complaint correlates of low elevations [e.g., "abdominal pain" for PHO ($T < 41$) and FAM ($T < 41$)] resulting from sample inclusion of physically ill patients referred for evaluation who evidenced no symptoms of psychological disturbance.

The susceptibility of personality scales with high content saturation to response biases such as defensiveness is illustrated by previously demonstrated negative relationships between subtlety of scale item content and the amount of K correction applied to the 10 clinical profile scales of the MMPI.

The second factor obtained in the current factor analysis highlighted the susceptibility of the majority of the content scales to such a defensive response set. A correlate of MOR ($T < 41$), "defensive," also suggested that lowered content scale scores are likely to result from intentional client distortion. Clinicians applying the content scales should be aware that high elevations represent significant probability correlates, whereas low elevations are less likely to suggest the absence of these symptoms—especially if Scales L or K obtain some elevation.

In spite of our hope, inspired by adherence to dustbowl empiricism, of discovering a number of unexpected correlates, few were obtained. One interesting finding was that REL, and to some extent FEM, elevations represent inhibition of acting out in male psychiatric populations. That is, the admission of religious beliefs is strongly associated with decreased substance abuse, marital conflict, and impulsive behavior, whereas low REL elevations relate to the replicated correlates "homicidal, impulsive, drug usage." Also, it appears that PSY ($T > 69$) in a predominantly nonpsychotic sample, reflects not only low base-rate psychotic behaviors, but it also suggests perplexity, suspiciousness, and worry.

Appendix

Proposed Interpretation of High MMPI Content Scale Scores

Organic Symptoms (T > 69)

This individual has admitted to a variety of sensory, motor, or general somatic concerns that may be related to psychological discomfort and general malaise as well as to reduced effectiveness in completing daily tasks. Clients who obtain high Organic Symptoms elevations may complain of lack of stamina and strength and may present physical symptoms that often indicate emotional conflict, such as problematic headache or back pain.

of interest in the environment, pessimism, self-criticism, and brooding. In client populations, social withdrawal, a negative self-concept, guilt feelings, and a reduced activity level may be suggested.

Poor Morale (T > 69)

Inventory responses reflect a pervasive lack of confidence in one's abilities and a history of failure, which is related to these perceived limitations. Clients who obtain high Poor Morale elevations may be insecure, despondent, withdrawn, intropunitive, and oversensitive, and may become easily upset by the actions of others.

Social Maladjustment (T > 69)

Endorsed item content reflects a lack of social skill and poise, discomfort in social interaction, and resultant inhibition and social isolation. In client populations, this lack of social supports may be associated with a negative self-image, feelings of despair or fearfulness, thoughts of suicide, or a defensive orientation characterized

Poor Health (T > 69)

A significant number of physical complaints are reflected by item endorsement centering mainly around the digestive system. Individuals who obtain high Poor Health elevations are often considerably worried about their health. Cardiac and pulmonary complaints are also occasionally reported.

Depression (T > 69)

This individual has admitted to symptoms associated with problematic depression, such as lack

by apathy and limited activity or compulsive attention to detail.

Manifest Hostility (T > 59)

This individual admits to problems in adjustment related to unmodulated expression of anger, resentment of perceived injustices, need for interpersonal dominance, and limited self-control. In client populations, the combination of hostility, moodiness, and impulsivity may be associated with assaultive or other antisocial or violent behavior.

Family Problems (T > 69)

Inventory responses include admission of pathology in and among family members. A history of poor relationships with parents is suggested, as well as the absence of positive supports in current family interactions, whether with parents, spouse, or extended family. Patient male: In adult male clients, admission of family pathology may reflect not only marital conflict but may also suggest intolerant, overreactive individuals and a negative self-concept. Drug abuse and other destructive behavior may be associated.

Authority Conflict (T > 59)

Endorsed item content reflects the belief that interpersonal relations are often exploitive in nature. Disregard for principles of ethical conduct and truthfulness is suggested, as well as a tendency to minimize the negative impact of antisocial behavior. In client populations, these attitudes may be associated with problematic overassertive and manipulative social relations. Conflict with relatives may result.

Feminine Interests (T > 59)

Inventory responses suggest an interest in pursuits traditionally labeled as feminine and/or dislike of activities stereotyped as masculine. Patient male: In male clients, this interest pattern may be associated with an indecisive, passive orientation that has proven to be problematic. Conflict may lead to confusion or self-

blame. Evaluation for suicidal ideation or previous attempts is suggested.

Phobias (T > 69)

This individual admits to a variety of fears and appears to be significantly uncomfortable in many situations. Clients who obtain high PHO elevations are viewed as more anxious, tremulous, worrisome, and phobic than most patients. Depression and social withdrawal may also be indicated.

Psychoticism (T > 69)

Inventory responses include admission of unusual experiences and beliefs, many of which may include a clearly paranoid component. In client populations, this response pattern often suggests an individual who finds comprehension of human motives and behavior difficult and is consequently suspicious of and worried about others. Symptoms associated with a psychotic adjustment, such as ideas of reference, hallucinations, and autistic or disorganized thought, may be present.

Hypomania (T > 59)

This individual's self-description suggests a fast personal tempo characterized by enthusiasm, cheerfulness, and perhaps irritability or emotional lability. Clients who obtain high Hypomania elevation are often described as immature, hyperactive, excitable, agitated, and restless. They are unlikely to respond intropunitively to conflict and may manipulate others to reach their goals.

Religious Fundamentalism (T > 59)

Endorsed item content reflects strong religious beliefs and religiously motivated behavior. In client populations, this orientation suggests a reduced probability of substance abuse, impulsive behaviors, and conflict with family members. Expression of strong religious beliefs may, at times, reflect a delusional system and associated thought disorder.

Effects of Film Modeling on the Reduction of Anxiety-Related Behaviors in Individuals Varying in Level of Previous Experience in the Stress Situation

Barbara G. Melamed
University of Florida

Richard Yurcheson, E. Louis Fleece, Steven Hutcherson, and
Roland Hawes
Case Western Reserve University

The influence of film preparation on 80 children undergoing three dental sessions (prophylaxis, dental examination, and dental restorative treatment) was evaluated with respect to (a) peer modeling versus demonstration of procedures and (b) amount of information. It was found by evaluating self-report and behavioral and visceral-arousal indices in a 2×2 factorial design that children exposed to a peer-model videotape presentation immediately preceding their own restorative treatment exhibited fewer disruptive behaviors and reported less apprehension than those watching a videotaped demonstration without a peer model. The modeling film elicited less heart rate activity in the subjects than the demonstration. The younger children (4-6 years) had lower self-reports of fear after viewing a more complete synopsis of what to expect, whereas the older children (8-11 years) had the lowest report of fears after viewing the peer model receiving a local anesthetic and brief intraoral examination. Children with previous treatment experience benefitted most from viewing the peer model undergoing the entire restorative procedure or a demonstration of the administration of local anesthetic in the absence of a peer model. Children with no prior experience were sensitized by being shown this demonstration. Thus, it was concluded that the age and previous experience of the viewer were important factors in determining childrens' fear-related behaviors after exposure to preparatory stimuli.

A large literature indicates that modeling, either live or symbolic (filmed), is effective in reducing fearful avoidance behaviors and in increasing adaptive behaviors in a wide variety of situations (Bandura, 1969; Bandura & Menlove, 1968). The effectiveness of modeling cannot be assumed without understanding what information needs to be presented, how this information can best get across to

the observer, and how the previous experience of the individual in the situation modifies these considerations.

The current investigation addressed these issues in children facing a real-life stress: dental treatment. Early attempts to introduce children to dental treatment by use of modeling films were successful (Adelson & Goldfried, 1970; Machen & Johnson, 1974). Melamed and her colleagues (Melamed, Hawes, Heiby, & Glick, 1975; Melamed, Weinstein, Hawes, & Katin-Borland, 1975) demonstrated reduced disruptive behavior and lower ratings of anxiety in children who had had no previous dental treatment experience after the children viewed a cooperative peer model as compared with children in a

control condition who observed either no film or a film unrelated to dentistry.

However, when film modeling was compared with systematic desensitization or a placebo (warm interaction with the hygienist), its effectiveness became less certain. Machen and Johnson (1974) and Sawtell, Simon, and Simeonsson (1974) found contradictory results. Much of the discrepancy between the findings of different investigators was most likely due to a lack of attention to the subject's prior experience with dental treatment and the presentation of information in the modeling situation.

This study compared peer modeling with a demonstration of the same dental personnel and procedures in the absence of a child model. Both of these videotapes provided the subjects with information about impending procedures, but in addition the peer model provided a sample of adaptive behaviors that should be emitted during treatment.

The second variable, amount of information presented, was used to evaluate whether the child observer needs to be exposed to each step of the procedure or whether exposure to the most feared event, the anesthetic injection, would facilitate modeling. Kleinknecht, Klepac, and Alexander (1973) suggested that dental fears can best be conceptualized as learned responses to painful stimuli during dental treatment.

The evaluation of the effectiveness of film modeling in relation to previous experience of the observer allowed us to look at the influence of information presented on avoidance behaviors that were generated by vicarious learning (no actual prior experience) or by some combination of classical, operant, and vicarious conditioning.

Method

Subjects

Eighty children between the ages of 4 and 11 were selected from the pedodontic clinic of University Hospitals, Cleveland, Ohio. Mentally handicapped or physically disabled children were excluded. Children who needed or had received previous extractions were excluded. Our sample consisted of 58 black children and 22 white children of homogeneous lower socioeconomic status. Assignment was made to one of five film groups with balancing for age, sex, race, previous dental experience, and initial report of fear on the Children's Fear Survey Schedule (Scherer & Nakamura, 1968) modified for dental-

related fears. There were 48 children who had had one or more cavities restored and 32 without prior treatment experience.

Procedure

Subjects were observed during two clinic visits. At the first visit the hygienist performed a standard prophylaxis (Session 1). Immediately afterward, a dentist examined the child's mouth and prepared bitewing radiographs (Session 2). The same dentist restored one or two cavities in a 30-minute appointment 7-10 days later (Session 3). The experimental manipulation involved exposure of children separately to one of five videotapes according to group assignment immediately prior to their restorative treatment session. Dentists were matched for experience, and both they and the independent observers were unaware of group assignment.

Groups

Long model. A 7-year-old black child is viewed undergoing a dental restorative treatment procedure. This 10-minute tape included the examination, injection, cavity preparation, and placement of the restoration. The boy remains cooperative and fearless throughout. The dentist and assistant are neutral. They instruct the model but do not use positive or negative reinforcement.

Long demonstration (demo). The 10-minute videotape was matched for the auditory tract, with the same dentist and assistant demonstrating the identical procedures without a child model in the chair. The dentist does say what behavior he expects in the child.

Short model. The same child is shown receiving the anesthetic injection followed by an oral examination. He remains cooperative throughout. This videotape runs approximately 4 minutes.

Short demonstration (demo). The dentist and assistant demonstrate the anesthetic injection and the oral examination without a child in the chair. This videotape runs approximately 4 minutes.

Unrelated control film. A videotape of *Evan's Corner* (Bostustow, 1969) pictures a 7-year-old black boy fixing a corner of the living room as his special place. This served as a control for subjects' exposure to a film.

Assessment battery. Previous research reporting low intercorrelations between different anxiety measures (Lang, 1968, 1978; Venham, Bengtson, & Cipes, 1977; Bernstein & Kleinknecht, Note 1) led us to examine different aspects of a child's subjective, behavioral, and physiological anxiety. Table 1 indicates the variety of measures used and the times at which they were assessed. On the first visit each mother (or guardian) completed a questionnaire about the child's behavior problems (Peterson, 1961) and one concerning her anxiety about dentistry and how she perceived her youngster would respond to dental treatment (Johnson & Baldwin, 1969). The Children's Fear Survey Schedule (CFSS; including 15 specific dental items) was administered orally to the child at this time and was repeated immediately prior to treatment

Table 1

Note. MAQ = maternal anxiety questionnaire; BPCL = Behavior Problem Checklist; CFSS = Children's Fear Survey Schedule; FT = fear thermometers; PSI = Palmar Sweat Index; BPRS = Behavior Profile Rating Scale; GSR = galvanic skin response; HR = heart rate; DRA = dental rating of anxiety; DRC = dental rating of cooperation; ORA = observer rating of anxiety; ORC = observer rating of cooperation.

after viewing the appropriate videotape. The children rated their degree of fear (on a 5-point fear thermometer) prior to the hygienist's treatment, following the dentist's examination, before and after the film, and following the restorative session. The Palmar Sweat Index (PSI; Thomson & Sutarman, 1953) was obtained at these same times. Observer ratings of anxiety were obtained during each session by an independent observer on the Behavior Profile Rating Scale (BPRS), a quantified measure of disruptive behavior. This instrument has demonstrated reliability and validity (Klorman, Ratner, King, & Sven, 1977; Melamed, Hawes, Heiby, & Glick, 1975; Melamed, Weinstein, Hawes, & Katin-Borland, 1975.) In addition, the dentist and the observer rated each subject on a 10-point scale of cooperation (1 = good, 10 = poor) and anxiety (1 = low to 10 = high).

Galvanic skin response and cardiac responses were measured during film viewing and treatment by means of a Grass polygraph. Data were stored on a Vetter FM tape recorder, and the heart rate data were available for analysis by means of a PDP-12 computer program. Five 30-sec samples from each film were selected for analysis. To compare videotapes of differing lengths, the total time of each videotape was divided into sixths. The five samples analyzed were taken at the first, second, third, fourth, and fifth one sixth of the videotapes starting with the third sample, which was chosen as the exact temporal middle of all films. Thus, the first two samples and the last two samples were the same proportional distance from the beginning and the end of each film. Heart rate difference scores were computed using median heart period in

a one-min prefilm resting baseline and subtracting from that the median heart rate period in milliseconds for each of the five samples for each individual.

In addition, the median heart rate for 10-sec intervals preinjection scene, during the injection, and postinjection were sampled. Difference scores were calculated by subtracting each from the preinjection value. These heart rate difference scores were analyzed to assess increments and decrements in heart rate in response to the specific content of the local anesthetic injection, regardless of the time into the videotape.

Results

There were no significant pretreatment group differences, except on the PSI. Each dependent variable was analyzed in a 2×2 factorial design to evaluate the effect of modeling versus demonstration, long versus short, and all possible interactions involving these factors and the repeated measure of time of assessment. Separate analyses were repeated with age, sex, race, and experience as separate main effects. Age was defined in three age blocks: 4-6 years; 6-8 years; and 8-11 years. Experience was dichotomized as no previous treatment versus previous restorations. A one-way analysis of variance was computed on all dependent measures to de-

termine whether an unrelated film control group, run after the main experiment, was significantly different from any of the treatment groups.¹ Appropriate subsequent *t* tests were used. All *p* values are for two-tailed tests.² An intercorrelation matrix of all measures at all assessment periods was obtained.

Modeling Versus Demonstration

The greater effectiveness of the modeling over the demonstration videotape was substantiated across most measures. Children viewing the modeling tapes reported fewer overall fears than children viewing the demonstration videotapes, $F(1, 56) = 4.26$, $p < .04$. The race of the subject did affect the subjective report. White children reported fewer fears than black children after viewing the modeling tape, $t(29) = 2.13$, $p < .05$, despite the fact that the child model was black. In fact, the black children reported fewer fears on dental items than whites after seeing the demonstration tapes, $t(31) = 2.6$, $p < .02$.

The behavioral measures were concordant with self-report findings. There was a borderline significance ($p < .06$), with the children viewing the modeling tape exhibiting less disruptive behavior than those viewing the demonstration of the same procedures. This interaction with sessions achieved significance, $F(1, 56) = 7.06$, $p < .01$, as illustrated in Figure 1. Immediately after viewing the peer model, children were less disruptive during

actual restorative treatment than those shown the demonstration version.

The type of videotape observed also yielded significant differences in the observer's ratings of anxiety and cooperation when age was taken into account. The 6- to 8-year-old children were rated as less anxious if they had seen the modeling film than if they had viewed the demonstration, $t(23) = 2.11$, $p < .05$, as illustrated in Figure 2. The same age group was also rated as more cooperative during restorative treatment if they had had the opportunity to view the peer model than if they had viewed the demonstration version for both observer ratings, $t(23) = 2.3$, $p < .05$, and dentist ratings, $t(23) = 3.3$, $p < .01$.

The Palmar Sweat Index data analyzed by covariance analysis showed a significant increase prefilm to postfilm, regardless of which videotape was seen. There was a significant correlation of the initial PSI with children's general fears ($r = .30$, $p < .02$) and specific dental fears ($r = .31$, $p < .01$), as reported on the Children's Fear Survey Schedule administered immediately preceding restorative treatment. The initial scores on the CFSS also correlated positively with the PSI taken immediately before the videotape was shown ($r = .31$, $p < .01$).

The heart rate data for the injection scenes also reflected a difference due to the type of film seen, $F(1, 51) = 4.69$, $p < .035$. There was a greater increase in children's heart

Figure 1. Degree of disruptiveness during dental treatment and type of videotape preparation.

¹ Because the subjects in the unrelated film group were all run after the completion of the videotape conditions, the results are suspect. The failure to replicate high levels of disruptive behavior found in our previous studies (Melamed, Hawes, Heiby, & Glick, 1975; Melamed, Weinstein, Hawes, & Katin-Borland, 1975) may be accounted for by the fact that all of these subjects were hooked up to a polygraph during treatment, thus limiting movement and likelihood of disruption. Therefore, only significant differences between the treatments and this condition were reported in this study. Appropriate replication is needed prior to interpreting the lack of group differences when one-way analyses of variance, including the control group, were performed.

² Appendix A, which has a table of all comparisons made, is available on request from the first author.

OBSERVER'S RATING OF ANXIETY

AGE

Figure 2. Observer's rating of children's anxiety by age and type of videotape preparation.

rates from the preinjection period to the during- and after-injection segments of the demonstration videotapes than in the heart rates of children who viewed the modeling versions. In fact, the group means in heart rate difference scores for the modeling conditions ($M = 8.69$ for during and $M = 11.55$ for postinjection) indicated a further decrease in heart rate as compared with the preinjection values.

Amount of Information

Although a main effect for length of the film was only apparent in the heart rate data, the self-report data did reflect an effect of film length when the age of the child was considered. No differences were found for the amount of information on any of the observational measures.

Children in the youngest age group, 4-6 years, reported fewer general fears after seeing the longer version as compared with the

short videotapes, $t(16) = 2.35$, $p < .05$. However, it should be noted that there was a main effect of age on the fear thermometer, another self-report measure. The youngest children gave higher ratings of self-reported fear than other age groups regardless of the type of film, $F(2, 65) = 4.95$, $p < .01$. The oldest children, 8-11 years, had the lowest report of dental-related fears after viewing

Figure 3. Heart rate difference scores for long and short videotapes across the five sampling intervals.

Figure 4. Degree of disruptiveness during dental treatment as effected by previous experience and type of videotape preparation.

the short model as compared with the short demonstration, $t(8) = 2.44$, $p < .05$.

Heart rate data did yield a significant effect of length of the film, $F(4, 204) = 3.07$, $p < .02$, with long films eliciting higher heart rate difference scores. In the interaction between length and interval, $F(4, 212) = 2.64$, $p < .04$, shown in Figure 3, it is clear that there exists a linear positive relationship between heart rate acceleration and time into videotape for the longer, more informative videotape. The children viewing the shorter tapes on the other hand showed an initial peak during the second, third, and fourth sampling points (film content overlaps in part with the injection segment) and a return to the initial heart rate difference scores by the end of the videotapes. In fact, the heart rate periods in response to the short versions never exceeded the prefilm baseline values, whereas the last two sampling points on the long version (film content shows restorative procedures after injection) exceeded the baseline values in the direction of increased heart rate (decreased heart period).

Previous Experience

The effectiveness of the different types of preparatory films on the behavior of the child

was influenced by previous experience, $F(1, 56) = 7.06$, $p < .01$. The difference caused by previous experience was not noted in any of the self-report measures.

Group differences are illustrated in Figure 4. The Behavior Profile Rating scores of Session 2 were used as a covariate in determining the significant differences between film types in groups defined as no prior experience versus previous experience because of the high correlations between these scores and the BPRS during Session 3 ($r = .38$, $p < .001$). The children with no prior experience showed significantly less disruptive behavior after viewing a short model or a long demonstration prior to their first restorative treatment, as compared with viewing the short demonstration ($p < .01$). In fact, the short-demonstration group showed higher degrees of disruption when compared with children who viewed the unrelated control film ($p < .02$). The children with previous treatment showed less disruptive behavior after viewing the long modeling film as compared with the long demonstration, $t(14) = -2.75$, $p < .007$. However, there were no significant differences between the long model and other videotapes, including the unrelated film. Overall, the dentists rated the

inexperienced children as decreasing in cooperation from the dental examination to the dental treatment, $t(48) = 2.0$, $p < .05$, whereas the change in cooperation for experienced subjects was insignificant. The correlations between BPRS scores for Session 2 and Session 3 were highly positive for experienced subjects ($r = .44$, $p < .002$), as were the dentists' ratings of their anxiety between Session 1 and Session 3 ($r = .63$, $p < .001$).

Intercorrelation Matrices

The data revealed good test-retest reliability within measures. Table 2 shows the high positive correlations that resulted between comparisons on the self-report measures. Table 3 indicates that the degree of disruptiveness (BPRS) during the first two sessions was highly related to the children's behavior during restorative sessions across all subjects. It was interesting to note that the greatest concordance between dentist and observer ratings of anxiety and cooperation occurred during the actual restorative treatment session. Table 4, which illustrates the comparison between measures tapping different systems (i.e., self-report and behavioral), is not unexpected in its sparse number of significant correlations. The most noteworthy is the fact that the children's self-reported dental fears just prior to the restoration correlated significantly with the degree

of disruptiveness during that session ($r = .29$, $p < .01$). This measure of anticipatory anxiety also correlated with the observer and dentist ratings of anxiety and cooperation during the treatment session.

The Table 5 measures of age, maternal anxiety, and general problem behaviors (BPCL) yielded some interesting correlations with the other dependent variables. Age correlated consistently with the child's self-report of anxiety, with younger children reporting more anxiety. Dentists and observers also tended to rate the younger child as more anxious. It is interesting that there was no significant correlation between the Behavior Problem Checklist and any of the BPRS measures. This would support the contention that this scale is measuring something other than just the general level of disruptiveness, hyperactivity, or management problems of the children. The relationship reported earlier in the literature between maternal anxiety and children's anxiety is not supported. In fact, the mothers' concern about their children is negatively associated with the children's self-report of anxiety prior to actual dental treatment.

Discussion and Conclusions

Peer Modeling Versus Demonstration

Does peer modeling reduce anxiety more than a demonstration of the same procedure?

Table 2

dures? There is evidence that this is true. Children who observed a peer-model film reported less dental and general fears than those who observed the demonstration film. In fact, the observational data are congruent with this in that children observing the peer model cooperated with the dentist and exhibited fewer disruptive behaviors. The children in the 6- to 8-year-old group were rated as less anxious and more cooperative if they had seen the peer-model film as opposed to a demonstration. Dentists also rated these children as more cooperative. These data support the general finding that children closest in age to the filmed model were the most susceptible. (It is interesting that black children did not reduce their self-reported fear after seeing a black child model as much as white children did.) The physiological data are also congruent. Higher sympathetic arousal (heart rate) was produced in response to the demonstration tape, whereas deceleration occurred in response to peer modeling. Thus, modeling films that show peers of similar age cooperating with dentists have a more favorable effect on the self-reported apprehension, actual behaviors of the

observing children, and autonomic indices of observers than do mere desensitization or exposure to impending events.

Amount of Previous Experience

The length of the film affected the self-reported apprehension, but not the behavior, of the children. The youngest children, ages 4-6, had the lowest reports of fear with longer versions of the film regardless of type of presentation (model vs. demo). The more information imparted, the more the heart rate difference scores increased. Therefore, it is not sufficient to give more information, as this can have a sensitizing effect, if the format of the presentation (model or demo) is ignored.

Effects of Previous Experience

The effects of having had prior dental experience were seen in terms of the children's behavior during dental restorative treatments. The dentists rated the children with no prior experience as being less cooperative during treatment than during the dental examination. The child who had al-

ready been to a dentist did not get significantly more anxious or disruptive during treatment. The effectiveness of different types of preparatory films on reducing disruptive behavior was related to previous experience. Children with no prior experience did best when given prior exposure to either a long demonstration tape or a short version with a peer model. They were sensitized by seeing a

short demonstration. On the other hand, children who have already experienced dental restorations behave much better if they view a long modeling version. Thus, when these children received maximum information regarding what to expect and how to behave, they were most cooperative during treatment. However, the lack of difference between the long model and the short demonstration at tests to the ability of some children to use their past experience in knowing how to behave, even in the absence of a model.

This study has raised important issues regarding the blanket assumption that filmed modeling reduces fear-related behaviors. It was found that there is a greater reduction of both self-reported and actual fear behavior during treatment when information is presented through a peer model. Whether this was due to greater information regarding behavioral expectation or whether viewing an identification figure increased modeling cannot be definitively stated. The physiological data would support that peer modeling produced a catharsis for model condition, since observers heart rates decreased with exposure.

The importance of age and previous experience in choosing appropriate preparatory material was borne out. The child most similar in age to the peer model being portrayed benefitted the most in his or her degree of cooperation. Race had a paradoxical effect, with white children showing lower self-reports of fear than blacks after seeing a black model.

In terms of previous experience, some important issues regarding the influence of prior knowledge on selection of type and format of information were raised. If the child has never actually undergone dental treatment but has formed a conception through vicarious processes, such as being told that a shot will be given, reminding him or her of this event in the absence of a model showing how to handle it (short demonstration) will sensitize him or her and increase the degree of disruption. On the other hand, the more experienced child will benefit most from being prepared for this noxious event briefly or by

seeing another child going through each step of the procedure in a cooperative manner.

Thus, the dental setting allows the researcher to investigate many questions regarding prevention and modification of stress responses, taking into account developmental and learning differences in information-processing abilities of the coping individuals.

A and B Undergraduate Interviewers of Schizophrenic and Neurotic Inpatients: A Test of the Interaction Hypothesis

Daniel F. Barnes
Counseling Center
Loyola University of Chicago

Juris I. Berzins
University of Kentucky

In an attempt to elucidate further the personological basis of the differential compatibility of A and B therapists with schizophrenic and neurotic patients, this study required A and B undergraduate volunteers (20 males, 20 females) to conduct 20-minute interviews with male state hospital inpatients (40 schizophrenics, 40 neurotics) in a 2 (interviewer A-B status) \times 2 (interviewer sex) \times 2 (patient type) factorial design. As expected from studies of the personality correlates of A-B status, many more B than A interviewers "looked forward" to conducting the interviews. Once in the interview situation, however, A-type interviewers elicited better self-disclosure from schizophrenic patients than did Bs, whereas the latter outperformed As with neurotic patients. The results are discussed in terms of a personological formulation that considers interviewer effectiveness to be a joint function of interviewer personality characteristics and the situational context.

The A-B variable emerged from a series of studies conducted by Whitehorn and Betz (1954) in the early 1950s. In these studies, therapists (arbitrarily labeled A and B) were found to be differentially effective with schizophrenic patients (As more effective than Bs). However, with neurotic patients, McNair, Callahan, and Lorr (1962) found Bs to be more effective than As. These findings suggested an "interaction hypothesis": As are more effective with schizophrenics than are Bs, whereas the latter are more effective with neurotics than are As. Subsequent analogue and clinical studies have generally supported the interaction hypothesis (e.g., Berzins, Ross, & Friedman, 1972; King & Blaney, 1977; Matthews & Burkhart, 1977).

This article is based on a study presented by the first author under the supervision of the second author as partial fulfillment of the research requirements leading to the PhD at the University of Kentucky.

The authors wish to thank Marian Grace, William A. Hunt, and Ronald E. Walker for their ideas and comments.

Requests for reprints should be sent to Daniel F. Barnes, Counseling Center, Loyola University of Chicago, 6525 North Sheridan Road, Chicago, Illinois 60626.

Several explanatory formulations of the A-B interaction effects (e.g., the "complementarity" hypothesis, perceptual-cognitive style compatibility) have been proposed. One such formulation can be called the personological hypothesis, which evolved from a study by Berzins, Barnes, Cohen, and Ross (1971), who showed that A-B differences can be explained in personality terms. Using the Personality Research Form (PRF, Jackson, 1967), they found that A-type persons were characterized by cautious self-expression, social ineptness, and a restricted cognitive scope, whereas B subjects appeared socially ascendant and "open" to complex experiences. The single most differentiating personality dimension was "harmavoidance" (As > Bs), denoting cautious avoidance of risk taking.

Berzins, Dove, and Ross (1972) cross-validated the Berzins et al. (1971) study with very large samples of college males and females, male therapists, and male college clinic patients. In spite of striking intergroup differences in PRF scale scores, A and B persons, across samples, showed distinctive personality profiles. In terms of five "core" scales, B-type persons were less harmavoid-

ant but more dominant, variety seeking, sentient, and "counterdependent" than were A-type persons.

The personality correlates of A-B status, in our view, should be regarded as depicting the *everyday* behaviors of A and B persons. Asking A and B college students to interview a schizophrenic state hospital inpatient, however, does not require the student to display everyday, accustomed behaviors. Rather, he or she is required to interact in a presumably "helpful" fashion with someone who is severely maladjusted. These situational demands, furthermore, need not be experienced similarly by As and Bs because of their differing levels of adaptation, self-confidence, and personal adjustment. Therefore, one would expect A- and B-type persons to display their "everyday" behaviors *before* they conduct an interview with a "state hospital patient" but not while interviewing. Accordingly, the following hypotheses were advanced.

1. Prior to meeting any patient, B-type persons should look forward to interviewing state hospital patients to a greater extent than should A-type persons.

2. Once in the situation, A-type persons should elicit better self-disclosure from schizophrenic patients and display greater non-verbal immediacy with them, whereas B-type persons should perform similarly with neurotic patients than should be the case under the opposite or "incompatible" pairing conditions.

3. After the interview, more positive reactions about the interview should be elicited from members of optimal pairings, as compared with members of nonoptimal pairings, as a consequence of greater interview success.

Method

Interviewers

A total of 131 student volunteers (56 males, 75 females), enrolled in the summer school session in psychology, filled out the PRF (Jackson, 1967) and the A-B scale (19 scored items). From this group, 40 students (the first 10 male and female As and the first 10 male and female Bs) were selected as interviewers. Using the Berzins, Dove, and Ross (1972) normative data, A status was defined by

scores between 0 and 7 for males and between 0 and 4 for females; B status, by scores 13 to 19 for males and 10 to 19 for females.

Patients

Schizophrenic ($n=40$) and neurotic ($n=40$) male inpatients at the Eastern State Hospital (Lexington, Kentucky) were selected on the basis of symptom clusters rather than formal diagnosis. Phillips and Rabinovitch (1958) distinguished three symptom cluster categories: (a) self-deprivation, turning against the self (TAS); (b) avoidance of others (AVOS); and (c) self-indulgence, turning against others (TAO). The first two categories, TAS and AVOS, were considered prototypic of neurotic and schizophrenic status, respectively. Using a procedure developed by Green (1971) and Welch (1971), a patient was classified as AVOS if the number of AVOS symptoms noted was equal to at least two and if the number of TAS plus TAO symptoms was less than the number of AVOS symptoms. Similarly, a patient was classified as TAS if he had at least two TAS symptoms and fewer (than TAS) AVOS plus TAO symptoms noted in the clinical folder.

Procedure

Each interviewer was to meet one AVOS and one TAS patient, with each interview lasting 20 minutes. The interviews were held in a moderately large one-way vision room that contained no furniture except for 15 chairs located on the perimeter of the room.

Before the first interview, each interviewer was instructed to "interview each patient as completely as you can by getting as much information as you can." To help the interviewer gain some degree of comfort and structure, the experimenter provided a deck of 12 cards, each with a possible interview topic on it. Of the 12 topics, 6 had been preterated as personal in content (e.g., "What aspects of your personality do you dislike?"), and 6 were neutral in content (e.g., "What is your favorite reading matter?"). After the interviewers had familiarized themselves with the topics (no directions were given to restrict the interview to these topics, however), each interviewer was asked casually if he/she was "looking forward to the interview," and was introduced to the patient and left to choose seats and conduct the interview. Following the first interview, the patient and the interviewer were asked (independently) how he or she felt about the interview. The same procedure was followed with the second patient. Both interviews were terminated by the experimenter's entering the room.

Dependent Measures

During the interviews, two advanced graduate students (one clinical, one nonclinical) observed

the interaction through the one-way mirror and rated selected aspects of the participants' behavior.

The main dependent measure was depth of patient self-disclosure, rated by both judges on a 0-3 scale (Berzins, Ross, & Cohen, 1970). Depth of self-disclosure ratings were assigned to every interview topic perceived as distinct by each judge; the topics were later subgrouped according to the personal-neutral distinction. In addition, at the 1st, 5th, 10th, 15th, and 20th minutes of the interview, the judges used multipoint scales to rate the interviewers' nonverbal behavior in 11 categories. These were taken from Mehrabian (1968) and included measures of "immediacy" or liking (physical proximity, eye contact, orientation of torso), relaxation or status (asymmetrical placement of arms and legs, sideways lean, reclining position, hands relaxed), and activity (facial expressiveness, rate and flow of speech).

The experimenter (the first author) also unobtrusively recorded interviewers' responses to the preinterview question ("Are you looking forward to the interview?"), and, after each interview, he asked the participants independently (a) "Did you like the interview?" (b) "Did you like the person you talked to?" and (c) "Throughout the interview, were you basically tense or relaxed?" Responses to these questions were coded as 0 or 1. Since the experimenter could not help being aware of the group membership of some patients and some interviewers, he attempted to ask all questions as impartially and equivalently as possible.

Design

The experimental design was a 2 (interviewer A-B status) \times 2 (interviewer sex) \times 2 (patient type), with the order of presentation of the last factor counterbalanced to control for order effects. There were 10 dyads per cell, with each interviewer having seen one AVOS and one TAS patient. Of the 40 interviewers, 20 saw the AVOS patient first, and 20 saw the TAS patient first.

Results

A correlational analysis was conducted to determine whether the A-B scale correlates in the PRF, originally demonstrated on much larger samples (Berzins, Dove, & Ross, 1972), were replicable within the summer school classes from which the interviewers were drawn. As expected, the A-B scale scores related negatively to the Harmavoidance and Succorance scales but positively to the Sentience, Dominance, and Change scales of the PRF, thereby replicating prior results.

Interjudge Reliability

Since the judges had strong agreement regarding the number of different topics covered by each interviewer, $r(78) = .93$, $p < .0001$, only those topics that were rated by both judges were considered. For individual topics ($n = 1,118$ across the 80 dyads), the interjudge coefficient for patient self-disclosure ratings was .69 ($p < .0001$), but the coefficient for mean self-disclosure per dyad, $r(78) = .89$, $p < .0001$, indicated that the judges used the self-disclosure rating scale in a consensual manner. Of the 11 nonverbal measures of interviewer behavior, three (eye contact, verbal fluency, and rate of speech) were not rated reliably (r s less than .27), but the remainder showed interjudge coefficients ranging from .64 to .98 (all p s $< .0001$). Only the latter were analyzed.

Preinterview Measures

We had hypothesized that prior to meeting any state hospital inpatient, the B-type interviewers would look forward to the interviews to a greater extent than A-type interviewers. This hypothesis was supported by the data, $\chi^2(1) = 16.94$, $p < .001$, with the effect especially pronounced among male interviewers, $\chi^2(1) = 16.36$, $p < .001$.

Intrainterview Measures

A four-factorial analysis of variance (incorporating the patient sequence as a separate factor) conducted across all intrainterview measures showed eight significant interaction effects, seven of which involved the patient sequence variable. That is, A-type interviewers in the AVOS-TAS sequence (AVOS patient seen first) and Bs in the TAS-AVOS sequence obtained more self-disclosure from patients than did interviewers paired oppositely. In general, although results with the "first patient seen" conformed to the interaction hypothesis, these trends also transferred themselves to the second interview, even though another (compatible or incompatible) patient now comprised the stimulus. These order effects replicate those of Berzins and Seidman (1968, 1969).

Since the interviewer's performance with the "first" patient cannot be affected by the impending second interview, analyzing the first interviews should afford a clearer appraisal of the interaction hypothesis in this experiment, although at a cost of statistical power (cf. Berzins & Seidman, 1968, 1969). Table 1 presents the results that were significant in three-factual (interviewer A-B status, interviewer sex, patient type) analyses of variance of all intrainterview measures.

Of the four significant patient-type main effects, three involved the self-disclosure variable. The TAS patients clearly were more self-disclosing than were AVOS patients, with regard to the personal, neutral, and total topics discussed within the interview. (The total topic category also includes the mean self-disclosures on topics introduced by interviewers, i.e., topics not on the cards.)¹ Since the AVOS patients may be regarded as more regressed than TAS patients, this result is not at all surprising and replicates the results of Green (1971) and Welch (1971) with Veterans Administration patients.

The other main effect involving the AVOS-TAS distinction (asymmetrical placement of arms by the interviewer) indicates that AVOS patients elicited higher levels of this index of relaxation (Mehrabian, 1968) than did TAS patients. This finding seems consistent with the notion that more schizophrenics exude lower status than do neurotics.

The main effects involving interviewer sex concerned one measure of nonverbal immediacy (proximity) and one measure of activity (facial expressiveness). Males sat closer to the patients than did females, but females were markedly more expressive than males. These results might best be understood in terms of sex role stereotypic behaviors.

The finding that A-type interviewers sat closer to the patients than did Bs is consistent with the results of the Berzins et al. (1970) study and of the Green (1971) and Welch (1971) studies, in which the A interviewer was rated as "warmer" than the B interviewer. Note, however, that this index of behavioral "approach" strikingly contra-

dicts expectations based on these interviewers' responses to the preinterview question, "Are you looking forward to the interview?"

Turning now to the two-way interaction effects in Table 1, it is clear that the main effects denoting the greater self-disclosure of TAS patients is qualified prominently by interviewers' A-B status. That is, A-type interviewers obtained equivalent self-disclosures from both types of patients, whereas Bs

¹ There were no main or interaction effects involving interviewer A-B status for the number of personal, neutral, extraneous, or total topics discussed. The average number of topics per dyad were 4.3 personal, 4.6 neutral, and 4.9 extraneous.

obtained considerably higher self-disclosures from TAS than AVOS patients. (Orthogonal comparisons between patient types within Bs were significant at $p < .005$ for total, personal, and neutral topics.) However, on personal and neutral (but not total) topics, A-type interviewers obtained significantly higher self-disclosures from AVOS than TAS patients (personal topics, $p < .01$; neutral topics, $p < .05$). Also, with TAS patients, B-type interviewers outperformed As on total ($p < .05$) and neutral ($p < .02$) but not on personal topics. Taken together, these results offer substantial support to the interaction hypothesis and are also consistent with the findings of Berzins et al. (1970) with addict patients, and those of Greene (1971) and Welch (1971) with Veterans Administration inpatients.

Two additional interaction effects (Interviewer A-B Status \times Interviewer Sex \times Patient Type), not shown in Table 1, involved one measure of nonverbal immediacy (orientation of torso) and one measure of relaxation (asymmetry of arms). Close examination of these effects, considered jointly, suggest that under compatible pairing conditions, male interviewers manifested greater immediacy but less relaxation than did male interviewers paired incompatibly. This attitude of poised attention appears consistent with the self-disclosure data and the interaction hypothesis. Female interviewers, however, did not follow this pattern; rather, they appeared to exhibit greater immediacy and relaxation with the AVOS patient than with the TAS patient. These differences invite clarification in further research.

Postinterview Measures

Our third hypothesis stated that members of compatibly paired dyads would show more positive postinterview reactions than members of incompatibly paired dyads. Since the variability of participants' reactions was constrained by ceiling effects (e.g., in only eight instances did an interviewer report having disliked the patient), the hypothesis was not supported statistically. However, when negative reactions were given, they

were consistent with our hypothesis and with the intrainterview self-disclosure data.

Discussion

The preinterview data clearly supported the first hypothesis and also offered behavioral validation of the interviewer's everyday personality characteristics, as reflected by PRF scale scores. However, since responses to the "looking forward to" question were solicited by the experimenter, these differences, their magnitude notwithstanding, require replication with better control over possible experimenter effects.

Before discussing the intrainterview results, the patient sequence factor bears examination. In the present study as in earlier analogues (Berzins & Seidman, 1968, 1969), undergraduate As and Bs paired compatibly and incompatibly "transferred" their differential performances with the first patient to the second patient. This "transfer" of performance differences associated with initial pairings to later ones, contrary to Chartier (1971), in no way cancels out the initial differences. Rather, these sequence effects, demonstrated in both analogue and in vivo settings, deserve recognition in the design of further research.

Turning now to the interviews themselves, the degree of support accorded the interaction hypothesis by the self-disclosure data seems important particularly because this study paired untrained, unsophisticated interviewers with markedly disturbed inpatients in a realistic interview situation. In spite of this arrangement, one that should work against ready, let alone differential, elicitation of self-disclosures, the A-type interviewers were able to elicit as much self-disclosure from AVOS (schizophrenic prototype) as TAS (neurotic prototype) patients, and they outperformed Bs with the AVOS patients.

Recalling that both in terms of PRF scores and responses to the looking forward question, A-type interviewers appeared more reticent than did Bs before encountering any patient, the finding that once in the interview, they in fact sat closer to their patients

than did Bs is intriguing also. Since increased physical proximity seems an unlikely correlate of cautious and reticent attitudes, it seems plausible that the A-type interviewer's "transformation" may have been eventuated by some aspect of the actual interview situation.

Our personological formulation assumes that the interviewer's behavior (effective or ineffective) is a function of the interviewer's own everyday personality characteristics and the situational context, the latter comprised at least of the demand that one function as a "helping agent," and the perceived characteristics of the patient, for example, degree of psychopathology. In everyday life, the A-type interviewer indeed may be cautious and submissive, and the B-type interviewer may be risk oriented and dominant. Upon encountering a markedly disturbed patient, however, the cautious and submissive A-type interviewer may perceive the regressed patient as someone whom he/she can help. In this sense, the regressed patient "liberates" A-type interviewers to behave effectively, whereas less disturbed patients may render these interviewers uncertain about the outcomes and may "inhibit" their effectiveness. On the other hand, with less disturbed patients, the dominant, risk-taking, self-assured B interviewer may perceive the situation as a reasonable challenge; contrariwise, the more disturbed patient may be experienced by the B-type interviewer as boring or even hopeless. The results of this study generally support this formulation.

Drug Abuse Patterns, Personality Characteristics, and Relationships With Sex, Race, and Sensation Seeking

Patricia B. Sutker, Robert P. Archer, and Albert N. Allain

Department of Psychiatry and Behavioral Sciences
Medical University of South Carolina

Interrelationships among sex, race, drug use patterns, and personality variables were examined in a sample of 84 chronic users of illicit drugs. Subjects were administered the Minnesota Multiphasic Personality Inventory, the Sensation Seeking Scale, and the Shipley Institute of Living Scale and were interviewed using the Background Information Questionnaire. Comparisons were made between sex and ethnic subgroups on personality and drug use variables using analysis of covariance and chi-square procedures for subjects classified into high-, medium-, and low-sensation-seeking groups. Blacks were characterized by lower levels of sensation seeking, less psychopathology, use of fewer drug categories, and later drug use than whites. Use and personality patterns among women differed little from those of men. Levels of sensation seeking were related to specific personality constellations, number of drug categories used, and motive for first alcohol use.

Research on the psychological characteristics of drug abusers has developed from attempts to describe and differentiate addicts from representatives of other clinically deviant categories. More recently, investigators have compared drug abuse subgroups (defined by race and sex) on personality dimensions or drug use patterns. Female and white drug abusers have been shown to demonstrate greater psychopathology than males and nonwhites (DeLeon, 1974; Olson, 1964), and ethnicity was found to be related to choice of drug type and variety used, particularly among men (Kaestner, Rosen, & Appel, 1977). Suffet and Brotman (1976) reported

lower rates of illicit drug use among women, but sex differences in drug use patterns have not been adequately specified.

Studies have also attempted to describe the association between personality characteristics and chronic drug use often without sex or race comparisons. Relationships have been demonstrated between sensation seeking and drug use patterns in college students (Zuckerman, Bone, Neary, Mangelsdorff, & Brustman, 1972) and hospitalized male veterans (Kilpatrick, Sutker, Roitzsch, & Miller, 1976). Combined elevations on Minnesota Multiphasic Personality Inventory (MMPI) Scales *Pd* and *Ma*, suggestive of exaggerated tendencies toward social nonconformity, have also been associated with chronic illicit drug use in men (Sutker & Allain, 1973; Zuckerman, Sola, Masterson, & Angelone, 1975) and women (Sutker & Moan, 1972), and relationships between drug choice and scores on sensation-seeking and MMPI dimensions have been described (Carrol & Zuckerman, 1977). For the most part, however, sex or race comparisons have been made independently, and their potential interactions in influencing drug use patterns or associated per-

This study was funded in part by General Research Support Grant No. 22620-A800 from the Medical University of South Carolina.

Special appreciation is expressed to Maggie Pike, Director of Odyssey House Louisiana and to Barry Pike, Director of the New Orleans Odyssey facility. The authors are also grateful to Walter Klimek and Caren Langford for assistance in data reduction and analysis.

sonality characteristics have not been fully explored. The present study was designed to address this area of limited investigation and to examine relationships between levels of sensation seeking, drug use patterns, and personality characteristics among chronic users of illicit drugs.

Method

Subjects were 84 drug abusers in residential treatment at Odyssey House Louisiana and included 38 white men, 18 white women, 22 black men, and 6 black women, a breakdown representative of program composition. Roughly 57% were addicted to opiates at program entry, and the remaining subjects were continuous users of stimulants (19%), depressants (14%), psychedelics (5%), or other drugs (5%). Treatment admission was nonvoluntary in over 90% of the cases. Subjects were selected from residents referred for psychological assessment at program promotion to Level 2, one of six hierarchical treatment stages. This selection procedure was used to minimize variation in length of time in current treatment (average of 3 months). Criteria for subject inclusion in data analyses were signed informed consent, demonstrated ability to read test items, treatment residence for 2 months, and history of drug abuse exceeding 2 years. Means for combined race and sex groups on age, education, and Shipley Institute of Living Scale scores were 24.29 years, 11.30 years, and 115.55, respectively. Preliminary Race \times Sex analyses of variance showed no differences between subgroups in age, education, length of current treatment, or length of continuous drug use. Differences were found on the Shipley, with blacks producing lower scores than whites, $F(1, 80) = 26.68, p < .01$.

Instruments used for data collection were (a) the Sensation Seeking Scale (SSS), a forced-choice questionnaire that measures individual differences in preferred optimal level of stimulation and yields five subscale and total scores; (b) the MMPI, scored for the 3 validity, 10 clinical, and Special Scales *A*, *R*, and *Es* (*K*-corrected *T* scores); (c) the Shipley Institute of Living Scale, a measure of verbal comprehension and problem-solving skills; and (d) the Background Information Questionnaire (BIQ), a structured interview developed by us to acquire information about personal history and patterns of drug use (e.g., age at first drug use; number of drug categories ever used; reason for first drug, alcohol, or opiate use; first drug used; and drug of choice). First responses to reason for drug, alcohol, and opiate use were each classified in one of three categories defined by Naditch (1975): reluctant use from social pressure, use for therapeutic intent, and use for pleasure or curiosity.

Sex and race subgroups were compared on 7 quantifiable BIQ measures using analysis of variance and on 6 SSS and 16 MMPI variables using analysis

of covariance procedures with the Shipley score as the covariate; *F* tests for simple effects were performed where significant interactions were identified. Chi-square analyses were performed to assess relationships between sex and race and five categories of BIQ responses, including reason for first drug, alcohol, and/or opiate use; first drug used; and drug of preference. Total SSS scores were used to divide subjects into three SSS groups: (a) low ($n = 14$), with scores 1 *SD* below the mean SSS score of 43; (b) medium ($n = 57$), with scores between ± 1 *SD* of the mean; and (c) high ($n = 13$), with scores 1 *SD* or more above the SSS mean. Preliminary analyses of variance indicated Shipley score differences between SSS groups, $F(2, 81) = 3.70, p < .05$, and a greater frequency of blacks (64%) in the low SSS group, $\chi^2(2) = 9.94, p < .01$. There were no significant differences in education or sex distribution. Thus, race and Shipley scores were used as covariates in analysis of covariance comparisons of SSS groups on MMPI variables, whereas analyses of variance were performed to compare groups on BIQ dimensions. Fisher's least significant difference tests were used to evaluate significant between-groups differences. Chi-square analyses were performed to test relationships between SSS groups and drug use patterns.

Results

Drug abuse subgroups defined by race differed significantly on SSS variables, and whites scored higher than blacks on Thrill and Adventure Seeking, $F(1, 79) = 18.79, p < .01$, General Sensation Seeking, $F(1, 79) = 9.18, p < .01$, and Total SSS, $F(1, 79) = 5.53, p < .05$. Sex differences in sensation seeking were limited, with men scoring higher than women only on Thrill and Adventure Seeking, $F(1, 79) = 5.78, p < .05$. Race and sex MMPI comparisons showed no differences between men and women, but whites produced higher scores on Scales *F*, $F(1, 79) = 4.03, p < .05$, *D*, $F(1, 79) = 4.61, p < .05$, *Pa*, $F(1, 79) = 4.32, p < .05$, and *Pt*, $F(1, 79) = 5.04, p < .05$, than blacks.

White drug abusers were younger than blacks at time of first drug, $F(1, 80) = 11.18, p < .01$, and first opiate use, $F(1, 61) = 6.51, p < .05$, and had used drugs from a greater variety of categories, $F(1, 80) = 6.06, p < .05$. Blacks and whites differed in drug of preference, $\chi^2(1) = 14.36, p < .01$. Opiates and depressants were endorsed by 100% of blacks and 62% of whites, whereas stimulants and hallucinogens were preferred

Figure 1. Mean Minnesota Multiphasic Personality Inventory profile patterns for low-, medium-, and high-sensation-seeking groups.

by 38% of whites and 0% of blacks. In male/female comparisons, men reported use of more drug categories, $F(1, 80) = 4.82$, $p < .05$, but women and men did not differ in reported drug preference. Race or sex differences were not significantly associated with reason for first drug, alcohol, or opiate use.

High, medium, and low SSS groups were characterized by variations in mean MMPI profile configurations (see Figure 1). Differences were found between groups on Scales *L*, $F(2, 79) = 4.22$, $p < .05$; *F*, $F(2, 79) = 3.19$, $p < .05$; *Hs*, $F(2, 79) = 3.49$, $p < .05$; *Hy*, $F(2, 79) = 4.50$, $p < .05$; *Pd*, $F(2, 79) = 4.23$, $p < .05$; *Ma*, $F(2, 79) = 10.00$, $p < .01$; *Si*, $F(2, 79) = 3.90$, $p < .05$; and *R*, $F(2, 79) = 8.93$, $p < .01$. Low sensation seekers scored higher than middle sensation seekers on Scales *L* and *Hs* ($p < .05$), *Hy* and *R* ($p < .01$) and high sensation seekers on *Hs* ($p < .05$) and *L*, *Hy*, and *R* ($p < .01$). High sensation seekers produced lower scores on Scale *Si* than those in low ($p < .05$) and middle ($p < .01$) groups and higher scores on Scales *F* and *Pd* than other groups ($p < .05$). High sensation seekers also produced more elevated scores on Scale *Ma* than medium sensation seekers ($p < .01$), who in turn produced

higher scores on *Ma* than those in the low SSS group ($p < .01$).

Sensation-seeking levels were significantly related to drug use patterns. High and middle sensation seekers reported earlier, $F(2, 81) = 3.15$, $p < .05$, and more varied, $F(2, 81) = 9.10$, $p < .01$, use of drugs than low sensation seekers. Although reason for first drug or opiate use and drug of choice did not vary as a function of SSS classification, reason for first alcohol use differed across groups, $\chi^2(4) = 12.96$, $p < .05$. Among low sensation seekers, 62% remembered their first use of alcohol as motivated by the influence of others, whereas 67% of high sensation seekers attributed initial use of alcohol to pleasure and curiosity.

Discussion

Findings indicate that race is an important factor to consider in understanding drug abuse phenomena, but gender may be of limited value in prediction of personality or drug use patterns for illicit drug users. Consistent with Kaestner et al. (1977), blacks demonstrated lower levels of sensation seeking and less psychopathology, reported use of fewer drug categories, showed preference for

depressants such as opiates over stimulants, and engaged in drug use later than whites. Less elevated scores on MMPI measures occurred among blacks despite the possibility that current MMPI norms, derived from white reference groups, exaggerate the *T*-score estimates of psychopathology for blacks (Gynther, 1972). In contrast to earlier research (DeLeon, 1974; Olson, 1964), results suggest that female drug abusers, in reference to their normative sex group, are no more psychologically deviant than men. Thus, the issue of sex-specific personality differences cannot be resolved without further comparisons across treatment and nontreatment conditions. Women and men also showed few dissimilarities on sensation-seeking measures with the exception of Thrill and Adventure Seeking, a cluster of items reflecting desire to engage in outdoor sports or activities involving speed or danger. Although women reported use of drugs from a fewer number of categories, no sex differences were found in age at first drug use, frequency of drug use, or drug preference.

Results support the hypothesis that there is a close relationship between sensation seeking, other personality dimensions such as sociopathy and neurotic involvement, and drug use patterns. High sensation seeking was related to use of more drug categories, earlier age at first drug use, and curiosity as a motive for initial alcohol use. Drug abusers classified as high sensation seekers scored higher on scales reflecting sociopathy, attitudinal deviance, and heightened activity and lower on measures indicating denial, hypochondriacal preoccupation, hysteria, and social introversion. Such individuals, relatively uninhibited by neurotic defenses, seem to be strongly motivated to increase external stimulation. In contrast, low sensation seekers produced higher elevations on measures of neurotic involvement, repression, and denial. Similar relationships among SSS and MMPI variables have been reported in correlational studies with prisoners (Blackburn, 1969) and alcoholics (Kish & Busse, 1969).

Present findings suggest that motives for drug use vary depending on such critical variables as race, sensation seeking, neurotic involvement, and sociopathy. It might be

hypothesized that chronic drug use is associated with exaggerated needs to attenuate unpleasant internal states or, conversely, to seek out external sources of stimulation. These assumptions provide a basis on which to match specific therapeutic packages to client personality characteristics and drug use patterns as well as a reasonable framework for investigating treatment outcome. For example, treatment of low sensation seekers might incorporate relaxation and social skills training to provide alternatives to drug use for reducing unpleasant internal states; high sensation seekers could be encouraged to identify activities and goals that provide gratifying and stimulating alternatives to the pharmacologic effects and concomitant life-styles of illicit drug use. Finally, motives for drug use and their relationships with such variables as race, sensation seeking, neurotic defenses, social introversion, and sociopathy should be explored systematically among drug experimenter, chronic user, treatment, and post-treatment populations.

Marital Satisfaction and Depression as Predictors of Physical Health Status

Robert L. Weiss and Barbara M. Aved
University of Oregon

This study investigated the multiple correlation between physical health status and a set of marriage-related "predictor" variables. Family practice physicians provided a sample of 104 married couples. Marital satisfaction, depression, number of visits to physician, and educational level were among the set of cross-validated "predictors" of reported physical health status. The correlation between physical health status and depression was significantly greater for wives than husbands. For wives, marital satisfaction and depression were related primarily through the uncontrolled variance in physical health status, whereas for husbands a significant relationship between marital satisfaction and depression remained for husbands when physical health status was partialled out. These findings support similar conclusions drawn by others.

Marital relationships provide a particularly attractive point of entry for the study of the relationship between behavior and health. Socially oriented conceptions of mental health focus either on interpersonal learning or on much broader psychosocial systems, such as collectives and communities. The marital unit provides the investigator with a vantage point within a minisystem from which attention can be directed downward toward individual or upward toward community determinants of behavior and adjustment. Nonetheless, empirical relationships between marital status and various conceptions of "health" have been studied only imperfectly (e.g., Crago, 1972; Vincent, 1973).

Some recently reported empirical relationships are as follows: (a) Marriage-related requests for professional mental health services run high; 58% of 2,000 consecutive

outpatient requests at a large university hospital were marriage related (Overall, Henry, & Woodward, 1974), whereas for psychological and social work settings, estimates run from 58% to 76% of all presenting problems. (b) Persons who have had multiple marriages, relative to the never married, show significantly less rated psychopathology (Overall, 1971). (c) Marital dissatisfaction may be part of a broader depressive spectrum disorder (Overall et al., 1974). The direction of causality between psychosocial variables and marital satisfaction has not been determined by these and the many other studies available in the literature. It is just as reasonable to assume that marital dissatisfaction causes depressive symptoms, poor job performance, or poor health as it is to assume that marital dissatisfaction results from these maladies.

The aims of this investigation were modest: We sought to establish the multiple covariations between reported physical health status and at least two face-valid person variables: marital satisfaction and depression. A similar approach, reported by Coleman and Miller (1975), determined that both self-reported and therapist-rated depression were significantly related to marital satisfaction, accounting for 14% and 23%

This article is based on a dissertation submitted in partial fulfillment of requirements for the PhD degree by the second author to the Department of Health Education, University of Oregon.

The authors wish to thank the physician members of the Lane County Academy of Family Practice for their cooperation in all phases of this study.

Requests for reprints should be sent to Robert L. Weiss, Department of Psychology, University of Oregon, Eugene, Oregon 97403.

of the variance in satisfaction ratings, respectively. Since physical health status and depression tend to covary (depression frequently involves somatic complaints), as do depression and marital satisfaction, the relationship between physical health status and marital satisfaction might be a spurious one.

The present study sought to establish the multiple correlation between a set of "predictor" variables and reported physical health status. Active patients of family practice physicians were selected for study, because physicians are often first-line providers of health services. They are an integral part of the psychosocial context of health status, since they frequently suspect that marital adjustment and depression, among other sources of distress, are concomitants (or even causal agents) of impaired health status. The multiple correlational analysis of health status and relationship variables was centered in this broader consumer-provider context. Physical health status has been a variable of psychological interest for those concerned with psychophysiological reactions and, more recently, life stress and somatic illness (cf. Holmes & Masuda, 1974; Rabkin & Struening, 1976; Rahe, 1974). Since the longitudinal study of changes in health status that occurs during marriage is impractical, the present study sought to provide cross-sectional data.

Method

Subjects

Family practice physicians at a regular meeting of the Lane County Academy of Family Practice were invited to participate in a study of the relationship between physical health status and variables related to marital satisfaction by providing names of couples who met the following criteria: (a) married for at least 2 years, (b) in a first marriage for both spouses, (c) between the ages of 22 and 48 years, and (d) wife not now pregnant. These criteria assured that couples were beyond the initial stages of marital accommodation and that medical problems associated with advancing age and/or pregnancy were excluded. The physicians were also asked to indicate whether, relative to their own practice, the persons they nominated were "overusers" or "normal users" of their services. The aim was to include representation of patients having psychosomatic involvements.

Four physicians participated by contributing a total of 280 persons (140 couples). (In almost all

instances, husbands and wives were patients of the same physician.) Each physician drafted a letter to his own patients, explaining that the study was "surveying adults about their health patterns," indicating an interest in identifying factors of family health potentially related to prevention, and assuring them that refusal to participate would not influence their relationship with their physician.

From the initial pool of 140 couples who had been contacted by letter, 135 were subsequently contacted by phone; 104 couples completed usable forms. Participation was refused in 23 cases; 5 couples had separated or divorced, 1 wife was pregnant, and 2 couples provided incomplete data. In the final sample, 18% of the subjects were designated by their own physicians as overusers (22% of the refusals had this designation). Individual physicians contributed from 17% to 38% of the final sample of 104 couples.

The typical subject was 30 years old, had had 2 years of college, and had been married for 8 years. Fifty-four percent of husbands and 24% of wives held white-collar and professional positions; 4% of husbands and 61% of wives were unemployed; 66% of the sample had two or more children. Couples were predominantly Protestant (57%), with 19% Catholics, 6% other, and 18% none. The resulting sample was a well-educated, possibly upper-middle class, group of couples who were rearing preadolescent children.

Measures

Physical health status. The Cornell Medical Index (CMI) was used as the measure of physical health status (Brodman, Erdman, Lorge, & Wolff, 1952); it consists of 195 items typically covered in an intensive medical history interview, ranging from systemic (sensory, respiratory, urogenital, etc.) to vague complaints associated with psychosomatic disorders. The questions sample bodily symptoms, past illnesses, family history, and affective states. The score is the total number of affirmative responses to the questions. In a sample of women scheduled for cancer surgery, both their preoperative and postoperative CMI scores were related to staff ratings of postsurgery invalidism ($r = .49$ and $.52$, respectively, $p < .05$); the pre-surgery to postsurgery CMI scores were also related ($\rho = .67$, $p < .01$; Bard & Waxenburg, 1957).

Self-Rating Depression Scale. The Zung (1965) Self-Rating Depression Scale (SDS) was used to assess depression. It consists of 20 self-statements, half of which are worded affirmatively and half, negatively. The SDS has been used widely in depression research for detecting the so-called "hidden depressions." Individual scores can range from 20 to 80 on this scale. Zung (1974) reviewed the literature on the reliability and concurrent and predictive validity of this measure. A number of studies have shown that for age-matched depressive patients and normals, 88% of the patients were detected by the SDS, whereas 12% of the normals were detected as "false positives."

Marital satisfaction. The Locke-Wallace Marital Adjustment Test was used to assess marital satisfaction and has been used widely in the literature as a reliable measure of marital satisfaction (Coleman & Miller, 1975; Locke & Wallace, 1959; Weiss & Margolin, 1977). Each spouse answers individually; scores of 100 or more generally indicate marital satisfaction, and scores below 100 indicate marital distress.

Activity level inventory. A 28-item version of the Inventory of Rewarding Activities, developed by the Marital Studies Program, University of Oregon, was used to assess how couples spend their leisure time. The scale reflects activities in home and community equally (e.g., "watching TV for more than 1 hour" and "go to a dance or party"). Respondents indicate whether during the last week each activity was engaged in alone or with spouse. Four activity scores were obtained: Home with spouse, Home without spouse, community with spouse, and community without spouse.

Questionnaire. In addition to the six measures described above, information on five demographic variables (age, number of annual visits to physician, years married, years residence in county, and education) was obtained.

Procedure

Persons to whom individual physicians had sent letters introducing the study were contacted by telephone and were given additional information. If they agreed to participate, an in-home meeting was then scheduled.

All data were collected in this meeting, which lasted approximately 45 minutes. The same interviewer (the second author) a registered nurse, conducted all interviews with respondents within a 3-month period.

When all interviews had been completed, the master lists of patients disclosing the initial "user" status designation were made available to the interviewer; the authors did not inform physicians which of their patients had or had not participated.

Results

Husband-Wife Comparisons

Wives, compared to husbands, on the average made significantly ($p < .01$ for all comparisons) more visits (annually) to physician, had more medical complaints (higher CMI scores), and reported engaging in more home alone activities. Husbands and wives did not differ significantly in mean Locke-Wallace marital satisfaction scores ($M_s = 111.4$ and 113.1 , respectively). The correlation between spouses' marital satisfaction scores was $.65$ ($p < .001$).

As an internal validity check, the 19 couples identified by their own physicians as "overusers" of medical services were compared to the 85 designated as "normal user" couples. In all comparisons, the females in the overuser group were significantly different from their counterparts in the normal group, whereas the males in both groups were comparable. As defined by their individual physicians, overuser relative to normal user females, on the average, scored 10 points higher on the CMI, 4 points higher on the SDS, and 7 points lower on marital satisfaction, and they were reported as having made twice as many visits to their physicians.

These comparisons between males and females are generally consistent with previous findings: Females reported more physical health concerns, made more visits to physician, and tended to score as somewhat more depressed on the SDS.

Predictors of Physical Health Status (CMI)

The 11 predictor variables were combined through multiple linear regression equations, with CMI as the dependent variable. Although the combination of self-report and demographic variables was selected for presumed relevance to marital interaction, multiple regression is particularly sensitive to fluctuations among correlations within successive samples. Consequently, the sample of 104 couples was divided at random into equal subsets of $N_A = N_B = 52$ couples. The neutral designation, Sample A and B, is preferred, since the dichotomy was formed after all data had been collected.

The results of major interest are presented separately in Table 1 for sex within each A and B subsample, as well as for subsample totals for each sex (total $N = 104$).

The zero-order correlations between each of the 11 predictors and CMI are listed for husbands and wives separately for subsamples and for totals, thereby allowing comparisons of within- and between-subsample fluctuations.

The multiple regression coefficients that resulted in each instance for the 11 predictors are listed below the zero-order correlations. The R^2 values indicate the amount

Table 1
Zero-Order, Multiple Correlation, and Validity Coefficients for Regression of CMI on Predictor Variables

Predictor	Husbands			Wives

Validity coefficient r	484	487	(485)	668	568	(620)

Note. $N_A = N_B = 52$. Decimals have been omitted. Validity coefficients are all significant at the .001 level. Averaged values appear in parentheses. For 50 df , $r_{.95} = .273$; for 102 df , $r_{.95} = .195$. CMI = Cornell Medical Index; SDS = Self-Rating Depression Scale; AHS = activities at home with spouse; AHS = activities at home without spouse; ACS = activities in the community with spouse; ACS = activities in the community without spouse.

^a Difference between these zero-order correlations is significant at the .002 level.

^b For Subsample A = B $df = 11, 40$; Total(s) $df = 11, 92$. F values for Husbands A, B, and Total: $F = 3.23, 2.79, 5.47$. F values for Wives A, B, and Total: $F = 7.72, 8.72, 12.79$. For all F values ≥ 3.23 , $p < .01$; $F = 2.79$, $p < .05$.

of CMI variance accounted for by the set of predictors.

Each of the multiple correlations was significant; the range of CMI variance varied from a low of 40% to a high of 70%. From the zero-order correlations in Table 1, it can be seen that the predictive ability of SDS, the depression variable, was most different for husbands and wives. (The significance of the difference between these correlations, based on $\sigma_{r_1-r_2} = .141$, yielded $p = .002$.)

For the two husband subsamples, the "best" replicated predictors included marital satisfactions, visits, and SDS; those for the wives included SDS and marital satisfaction, similar to husbands. Nonreplicating predictors for the wives included education, visits, years in county, and activity in community without spouse.

Finally, the last row of Table 1 lists the validity coefficients determined by "double cross-validation"; the beta regression

weights, derived from each within-sex subsample, were applied reciprocally to the other. For example, the betas for Sample A wives were applied to Sample B wives, and those for Sample B were applied to Sample A. The Pearson product-moment correlation coefficients between the predicted CMI and observed CMI scores thus yield a validity coefficient based on the adequacy of one set of beta weights to predict from the raw data of a different sample. This particular choice of cross-validation underestimates the goodness of fit, since only one half of the data is used to determine the weights.

From Table 1 it can be seen that all validity coefficients were highly significant, although those for husband samples were substantially lower than the estimates for wives.

To further specify the relationship between CMI (1), marital satisfaction (2), and SDS (3), the partial correlation ($r_{12.3}$) was calculated for husbands and wives separately. The respective partial correlations were $-.35$

and $-.28$ ($ps < .01$). From Table 1, the comparable zero-order correlations are $-.468$ and $-.459$.) Reported physical health status and marital satisfaction were mediated, in part, by variations in depressiveness scores; the partial correlations remained statistically significant.

When the relationship between marital satisfaction and depressiveness was statistically controlled for differences in physical health status scores, the partial correlations dropped from their respective zero-order correlations of $-.486$ and $-.401$ ($ps < .01$) to $r_{12.8} = -.334$ ($p < .01$) and $-.159$ (ns), for husbands and wives, respectively. The CMI and SDS share many physical items in common (e.g., "I have trouble with constipation."). The significant residual correlation between SDS and marital satisfaction suggests that marital (dis)satisfaction and depressive affect are likely to be found together for husbands, although the magnitude of the correlation was small. For wives it appears that common variance from the physical symptom items accounts for the CMI \times MS relationship, which is understandable given the size of the zero-order correlation between CMI and SDS in Table 1.

Discussion

This has been an investigation of the network of covariations between physical health status on the one hand and marriage-related variables on the other. It differed from others (e.g., Coleman & Miller, 1975) by (a) drawing nonclinical spouses from the context of an ongoing consumer-provider relationship, namely, patients and their family practice physician providers, and (b) providing a cross-validation of the correlates of health status. Well-educated couples in first marriages who reported above average marital satisfaction served as respondents. Physicians identified a relatively small number of their patients as overusers of their services to ensure inclusion of typical "psychosomatic" cases. (Descriptively, these cases were women who differed significantly from their counterparts on all relevant variables, e.g., annual visits, CMI, and SDS.)

The "best predictors" to CMI among the zero-order correlations that replicated within same-sex subsamples were SDS, marital satisfaction, visits, and to a lesser extent education. The amount of physical health status variance accounted for by SDS variance differed significantly for husbands and wives (14% and 45%, respectively).

When all 11 predictors were combined into multiple regression equations, the amount of CMI variance accounted for increased substantially, ranging from 40% to 60% for husbands and wives, respectively. Overall, CMI scores were better predicted for wives than for husbands.

Among the best predictors of physical health status, depression and marital satisfaction are the most interesting. (Persons reporting greater numbers of physical symptoms tended to see their physicians more than others, and those with more years of education reported fewer physical symptoms.)

Whereas the relationship between health status and marital satisfaction was only slightly reduced when unplanned variations in depression were statistically controlled, the correlation between marital satisfaction and depression for wives became insignificant when health status variance was controlled.

Coleman and Miller (1975) reported similar results for an older, less-educated sample of mental health clinic outpatients and their spouses. (The same pattern of mean differences between husbands and wives on depression and satisfaction ratings was observed in the two investigations.) For combined samples of husbands and wives, the relationship between marital satisfaction and depression was $r = -.38$ ($p < .01$) and $r = -.43$ ($p < .01$) in the Coleman and Miller and the present studies, respectively. They also found a similar pattern of difference between marital satisfaction and depression relationships for husbands and wives (i.e., $rs = -.66$, $p < .01$, and $-.25$, $p = .10$, respectively). In the present results the Marital Satisfaction \times SDS relationship became insignificant for wives when the uncontrolled variations in physical health status were accounted for. (In both studies a significant inverse relationship was found between husbands' mari-

tal satisfaction and wives' depression scores, but in neither case were wives' depression and husbands' marital satisfaction scores significantly related.)

Coleman and Miller (1975) concluded that marital satisfaction and depression for females were essentially unrelated, and the present results lend some support to this view. Bernard (1972), on the other hand, concluded that wives suffer far greater mental health hazards and that they present a far worse clinical picture than do husbands. Drawing mainly on sociological studies (e.g., Knupfer, Clark, & Room, 1966), she stressed the double standard of mental health that essentially builds into "our standards of mental health for women the defects necessary for successful adjustment in marriage" (p. 52). More recently Overall et al. (1974) have presented statistical evidence that both a family history of marital discord and what might be labeled a "depressive spectrum disorder" independently predict the likelihood of outpatients' complaints of marital discord.

All of the available data are based on correlational analyses. This approach may be helpful in suggesting which aspects of relationship living have significance for physical health status. A direct test is needed whereby marital therapy can be shown to improve physical health status of the partners; depending on one's point of view, this may occur more for husbands than for wives. The present investigation is merely another step toward specifying the probable contribution of separate variables.

Sexual Fantasies of Females as a Function of Sex Guilt and Experimental Response Cues

Denise Moreault and Diane R. Follingstad
University of South Carolina

This study investigated the effects of response cues (erotic, romantic, or neutral) and level of sex guilt on the self-reported sexual fantasies of females. Undergraduates completed a sex guilt inventory, a mood adjective checklist, a fantasy theme checklist, and ratings of their affective responses and physiological arousal associated with the writing of the fantasies. High sex guilt females preferred fantasy themes indicating a lack of responsibility for engaging in sexual interaction. Subjects in the erotic fantasy condition wrote more explicit fantasies and described more varied content. Arousal seemed to be affected by the response cuing in the predicted direction but not by the subjects' guilt levels. Sex guilt level seemed to be a better predictor of affective responses, such as guilt and embarrassment, than the response cuing. The results suggest that sexual fantasy behavior may be part of a cluster of sexual behaviors governed by an individual's level of sex guilt. The demonstration that fantasy production seemed to be influenced by situational demands has implications for collection and use of fantasy information by both clinicians and researchers.

Until recently, sexual fantasy behavior in females has remained a relatively unexplored area except among clinicians studying cases of sexual deviation (e.g., Abraham, 1922; Eidelberger, 1945; Sterba, 1921; Wulff, 1942). It has been viewed as pathological or at least symptomatic of poor heterosexual relations, especially when the fantasies included other than conventional heterosexual practices (Hollender, 1970). Only one experimental study (Hariton & Singer, 1974) in this area established the normalcy of sexual fantasies, substantiating Kinsey, Pomeroy, Martin, and Gebhard's (1953) normative demographic data. This study, however, only correlated a few personality variables with fantasy, and predictability from their data was limited.

The limited information regarding females' sexual fantasies has been complicated by a treatment of sexual fantasy as a homogenous entity in which a sample of individuals are simply asked whether or not they engage in

fantasy during sexual experiences. No investigation to date has selected subjects along a personality trait dimension to determine whether certain individuals are more likely to fantasize or are affected differently by fantasizing. In addition, specific operationalized parameters of fantasy behavior (e.g., themes, vividness, number of acts and organs portrayed) that potentially could yield more precise information have been sacrificed for simple assessment of the presence or absence of fantasies. Researchers attempting to collect data regarding sexual fantasies have also neglected to study the circumstances or conditions under which fantasies are produced and disclosed to others, thus ignoring the demand characteristics of the situation. The purpose of this study in assessing females' sexual fantasy behavior was to determine whether fantasies were tied to a personality trait and/or were under situational stimulus control.

A personality dimension that has been shown to predict a variety of sexual behavior patterns is the construct of sex guilt as developed, defined, and measured by Mosher (1966). Sex guilt has been defined as "a

Requests for reprints should be sent to Diane Follingstad, Department of Psychology, University of South Carolina, Columbia, South Carolina 29208.

generalized expectancy for self-mediated punishment for violating or for anticipating violating standards of proper sexual conduct" (Mosher & Cross, 1971, p. 27). Since sexual fantasies are likely to be related to other sexual behaviors, the level of sex guilt in individuals was expected to influence the content and explicitness of fantasies. Subjects scoring high in sex guilt compared to subjects low in sex guilt have been found to produce or recall less information relating to sexuality (Galbraith & Mosher, 1968; Langston, 1973; Schwartz, 1973), to evaluate less conventional and explicit sexual activity negatively (Mosher, 1973; Ray & Walker, 1973), and to report more guilt and embarrassment following exposure to sexual stimuli (Mosher & Greenberg, 1969; Schill & Chapin, 1972). Based on the literature regarding the effects of levels of sex guilt, the fantasies of high sex guilt (HSG) subjects were expected to be fewer in number, shorter, and less vividly remembered; to exhibit less thematic variety; to be more restricted in terms of specific sexual acts and organs described; and to contain romantic heterosexual themes. Following the writing of their own fantasies, subjects with high levels of sex guilt were expected to report more guilt and embarrassment than low sex guilt (LSG) subjects.

There have been conflicting data regarding how level of sex guilt affects sexual arousal. Mosher (1973) suggested that most females experience arousal regardless of their sex guilt level, whereas Schill (1972) suggested that subjects with little sex guilt report more arousal. It was predicted that subjects would report arousal to sexual fantasy stimuli independent of their level of sex guilt. In light of Schmidt's (1975) findings that females report a greater degree of arousal when rating genital sensations than when rating general arousal, sexual arousal needed to be measured by a variety of ratings.

Some investigators have been cognizant of the fact that the atmosphere and context in which self-disclosure takes place has an effect on the data that subjects produce (Galbraith & Mosher, 1968; Mosher, 1965). The stimulus conditions under which sexual fantasies are reported have important implications for

research and clinical practice, which relies on self-reported fantasy of subjects. No study, however, has attempted to manipulate the conditions under which fantasies are produced to determine which conditions are more conducive for, and differentially predictive of, the quality and quantity of subjects' fantasy production. Routh, Warehime, Gresen, and Roger (1973) found that giving subjects explicit instructions to write sexy stories as opposed to simply writing stories produced sexier stories. This would imply that fantasy content is under the influence of instructional set and experimental demand characteristics. Also, no researchers have investigated the effect of a romantic stimulus devoid of explicit sexual content on the sexual responsiveness of subjects (Schmidt, 1975).

Based on the research regarding instructional set, the following hypotheses were tested in relation to sexual fantasy production: (a) Erotic (i.e., sexually explicit) examples of fantasies would result in more and longer fantasies, more explicit imagery, and more variation in thematic content than romantic examples; (b) sexual fantasies would be longer, more varied, and more explicit for those females given sexual fantasy examples than those given a nonsexual fantasy stimulus; (c) individuals in a neutral fantasy condition would report less guilt and embarrassment than those in the erotic and romantic stimulus conditions, although erotic fantasy cues would produce a higher degree of sexual arousal in females than either romantic or neutral cues; and (d) a purely romantic stimulus would be less threatening than an erotic sexual stimulus for females with high sex guilt, resulting in more fantasy production with a greater variety of themes but less sexually explicit content.

The current literature on sexual fantasizing in clinical settings has been concerned with using fantasy to change deviant sexual behaviors (e.g., Evans, 1968; Marquis, 1970; Marshall, 1973) and assessing its effect in increasing sexual pleasure and treating sexual dysfunctions (e.g., Kaplan, 1974; Kline-Graber & Graber, 1975). Knowing the effects of level of sex guilt on a female's fantasizing behavior as well as the conditions most conducive for producing sexual fantasies should

contribute to the effective application of fantasy techniques in clinical settings.

Method

Subjects

Undergraduate females, ranging in age from 17 to 25, volunteered from a variety of psychology classes in a large southern university. One hundred fifty-three subjects were randomly assigned initially to three experimental conditions, receiving either erotic, romantic, or nonsexual fantasy examples. The final sample of 90 heterosexual subjects consisted of the 30 females in each condition who had the highest and lowest levels of sex guilt as measured by an inventory tapping self-reported guilt feelings. Ethical guidelines with regard to use of human subjects were followed.

Experimenter

The experimenter delivered the instructions and absented herself while the subjects completed the measures. To decrease the fear of external censure, the experimenter attempted to present herself as a nonevaluative and scientific individual (Galbraith & Mosher, 1968; Mussen & Scodel, 1955).

Measures

Mosher Forced-Choice Guilt Scale—Female Form. The Sex Guilt subscale consists of 20 Likert-type items with four response options. Split-half reliability of the scale produced a correlation of .95. Convergent and discriminative validity of the Mosher guilt scales have been demonstrated (Mosher, 1966; Mosher & Cross, 1971) with the Sex Guilt subscale being significantly different from the other guilt measures.

Fantasy essays. Subjects were asked to write down all the personal sexual fantasies that they could recall having experienced.

Fantasy Theme Checklist. This checklist was derived from the list developed by Hariton and Singer (1974) and was expanded to include themes reported in a compilation of women's sexual fantasies by Friday (1973). Subjects checked any of the 22 fantasy themes that they had experienced as part of their own fantasies.

Mood Adjective Check List (MACL). This measure of 49 adjectives was originally developed by Nowlis (1965) to prompt subjects to label their changing moods and was modified by Mosher and Greenberg (1969) to include 7 adjectives measuring sexual guilt and 7 adjectives measuring sexual arousal. Previous studies have demonstrated that changes in guilt and arousal as measured by adjective ratings are a viable measure of change due to experimental manipulation (Mosher & Greenberg, 1969; Okel & Mosher, 1968).

Sexual arousal, vividness and embarrassment rat-

ings. Subjects rated whether or not they experienced arousal, their subjective degree of sexual arousal on a 7-point scale, and the strength of genital and/or breast sensations in response to the writing of their fantasies. Embarrassment as a result of the fantasy reporting and the vividness (i.e., ability to remember facts and details clearly) of the fantasies while recording them were rated on a 5-point scale.

Experimental Conditions

Subjects in the three stimulus conditions were presented either with three erotic, three romantic, or three neutral examples of fantasies prior to writing their own fantasies. Heterosexual fantasies for the erotic (i.e., sexually explicit) condition were adapted from Friday's (1973) book, which reports fantasies solicited from the general population. Romantic fantasies, focusing on an emotional heterosexual relationship without mentioning sexual acts or organs, were solicited from undergraduate females. Nonsexual fantasies were solicited from other undergraduate females who wrote fantasies containing no sexual content, such as career aspirations or adventures.

Several fantasies of each type were given to a panel of five female judges (ranging in age from 23 to 31) prior to the experimental sessions and were rated by the judges along the dimensions of erotic, romantic, or personally pleasing for the three fantasy conditions mentioned above. The three fantasies rated highest in each condition were used as the experimental stimuli.

Procedure

Subjects in each experimental group were given the measures in three phases during a 1½-hour experimental session. Approximately 25 subjects were present at each session. In the first phase, subjects were administered the Mosher Forced-Choice Guilt Scale and the MACL. Following this, subjects were informed that the study involved reading and writing sexual materials. Subjects were informed that they could leave at any time.

To promote a permissive atmosphere, the second phase began with instructions informing subjects that sexual fantasies and thoughts were normal, usual experiences. The experimental stimuli were introduced with an explanation that reading examples of fantasies might put subjects in the mood for writing their own. Subjects were given the set of examples appropriate to the condition that they were in, and they returned the stimulus materials to the experimenter before proceeding. Explicit instructions of what constituted sexual fantasies were given in order that subjects would understand that either detailed or vague mental scenes, pictures, or stories that they had experienced would be appropriate to report. They were also told that these fantasies were to be written down in as much detail as possible.

During the third phase, the following measures were administered: the Fantasy Checklist; the sexual arousal, vividness, and embarrassment ratings; and a second administration of the MACL. Subjects were debriefed after the experiment concluded.

Scoring of Subjects' Fantasies

Subjects' fantasies were scored according to (a) number of sexual fantasies; (b) length of longest sexual fantasy; (c) total number of words written; (d) explicitness of the sexual fantasy (i.e., the total number out of 7 possible sex organs and 12 possible sex acts that were mentioned either in physiological, medical, or slang terminology in the fantasy containing the highest frequency of acts and organs mentioned); and (e) total of 4 possible content areas of sexual fantasies (i.e., typical heterosexual activities; heterosexual oral-genital contact; group sex; rare or unusual sexual acts).

Results

Eighteen subjects were dropped from the original sample; 8 subjects reported having engaged in homosexual activities, 6 test records were incomplete, 1 subject was over the required age limit, and 3 subjects left the experiment after the nature of the study was revealed. The 15 subjects scoring highest and the 15 scoring lowest on sex guilt in each of

three experimental conditions comprised the final sample ($N = 90$). Ninety-eight percent of the sample wrote at least one sexual fantasy, and all subjects checked at least two fantasy themes.

In this 2×3 factorial design, the means of the HSG and LSG subjects across fantasy stimulus conditions were as follows: LSG in the erotic condition = -52.6; LSG in the romantic condition = -58.5; LSG in the neutral condition = -53.2; HSG in the erotic condition = -1.2; HSG in the romantic condition = -1.5; and HSG in the neutral condition = -.4. One-way analyses of variance (ANOVAS) performed on the means of sex guilt scores for LSG and HSG subjects across experimental conditions revealed no significant differences, supporting the random assignment of subjects to conditions and lending confidence to the assumption that any differences in dependent variables can be viewed as a result of the experimental manipulation and subjects' sex guilt level.

The hypothesis that HSG and LSG subjects would differ in the characteristics of their sexual fantasies was largely supported (see Tables 1 and 2 for means, standard deviations, and F values). One-way ANOVAS

Table 3

Chi-Square Results of Differences Between Sex Guilt Groups in Descriptions of Sex Organs and Sex Acts in Their Sexual Fantasies

Sex organ	χ^2	Sex act	χ^2
Breast	.05	Kissing	1.73
Penis	6.69**	Manipulation of female breast	2.19
Clitoris	5.94**	Manipulation of female genitals	.14
Vagina	.54	Intercourse	
		Ventral-ventral	4.84*
		Oral contact with male genitals	3.04
		Oral contact with female genitals	3.42
		Homosexuality	3.60

Note. For all significant differences, low sex guilt subjects were more explicit than high sex guilt subjects. Cell frequencies for the remaining three sex organs and five sex acts were too small to test. $df = 1$ in all cases.

* $p < .05$.

** $p < .01$.

indicated that LSG subjects demonstrated less sexual inhibition than HSG subjects in terms of sexual explicitness, expressiveness, and responsiveness to the stimuli: for total words, $F(2, 84) = 9.75$, $p < .01$; for total number of fantasies, $F(2, 84) = 4.91$, $p < .05$; for number of sex acts, $F(2, 84) = 3.85$, $p < .05$; for variety of content, $F(2, 84) = 3.57$, $p < .05$; and for number of fantasy themes checked, $F(2, 84) = 6.39$, $p < .01$. As predicted, there were no significant differences between HSG and LSG subjects on level of arousal or breast and genital sensations, even though LSG subjects increased the amount of arousal experienced significantly more from pre-MACL to post-MACL than HSG subjects, $F(2, 84) = 3.86$, $p < .05$. More embarrassment was reported by HSG subjects, $F(2, 84) = 23.57$, $p < .001$, and they also reported experiencing their fantasies less vividly, $F(2, 84) = 13.94$, $p < .001$ (see Table 2). LSG subjects reported experiencing less guilt following the sexual stimulation (postguilt) than HSG subjects, $F(2, 84) = 5.12$, $p < .05$ (see Tables 1 and 2), although HSG subjects in comparison to

the LSG subjects did not significantly increase the amount of guilt (Guilt \times Time) experienced due to the experimental manipulation (see Table 2).

A chi-square analysis was performed on each sex organ and sex act mentioned in the fantasies of LSG and HSG subjects. Results indicated that LSG subjects mentioned the words *penis*, *clitoris*, and *sexual intercourse* significantly more often than HSG subjects. No other significant differences between groups were found for sex organs and sex acts that were stated in the fantasies (see Table 3).

HSG subjects checked 30% fewer themes on the Fantasy Checklist as compared to LSG subjects. For each sex guilt group, the number of times a theme was checked was compared to the total number of themes checked. A nonparametric test of the significance between two proportions was performed comparing the percentage of each theme to the total themes for the LSG and HSG groups. LSG subjects responded significantly more often to two themes: "I relive a previous sexual experience" ($z = 2.03$, $p < .05$), and "I have pretended that I am making love to a man that I am acquainted with other than my current lover" ($z = 2.65$, $p < .01$). HSG subjects responded more frequently to two themes related to being dominated sexually: "I imagine that I am being overpowered or forced to surrender," and "I enjoy imagining that I am being dominated sexually and that I am helpless" ($z = 2.78$, $p < .01$, and $z = 2.25$, $p < .05$, respectively). HSG subjects also checked "Thoughts of an imaginary lover or a stranger enter my mind" ($z = 2.17$, $p < .05$), and "I imagine that I am so beautiful that men cannot resist me" ($z = 2.23$, $p < .05$) significantly more often than LSG subjects.

As predicted, ANOVAS on the characteristics of subjects' fantasies resulted in significant differences in response to the conditions of erotic, romantic, or neutral response cues (see Tables 1 and 2). The length of fantasies differed between groups, $F(2, 84) = 4.01$, $p < .05$, and post hoc analyses (see Table 4) revealed that subjects in the erotic fantasy condition wrote longer fantasies than subjects in the romantic condition, $t(58) =$

Table 4
t-Test Results by Condition for Significant F Values

Dependent variable	Erotic vs. romantic	Erotic vs. neutral	Romantic vs. neutral
Length of fantasy	2.68**	1.69	1.23

^a Measured by Multiple Adjective Check List.

* $p < .05$.

** $p < .01$.

2.68, $p < .01$. Both the number of sex acts and sex organs mentioned varied across groups, with subjects in the erotic condition writing more explicit fantasies than those in both the romantic condition and the neutral condition. The variety of content described in each experimental condition produced significant differences, $F(2, 84) = 3.57$, $p < .05$, with post hoc analyses indicating that the differences were a result of the erotic group subjects, who wrote fantasies with more varied content than those in the romantic fantasy group, $t(58) = 2.25$, $p < .05$. Contrary to predictions, the number of fantasies, total number of words written, and number of themes checked were not significantly affected by experimental conditions.

Presence in different experimental groups did not produce differences in the degree of reported guilt, embarrassment, or vividness of the fantasy experience. However, subjects in both the erotic and romantic fantasy groups reported more sexual arousal and the presence of sexual sensations more often than those in the neutral fantasy group. A greater degree of genital and breast sensations were reported by subjects in the erotic group than those in either the romantic or neutral groups, and subjects in the romantic fantasy group reported more genital and breast sensations than those in the neutral group.

As seen in Table 2, none of the predicted interactions between levels of sex guilt and

experimental condition on sexual fantasy were significant.

Discussion

Both sex guilt level in subjects and experimental fantasy cues demonstrated strong effects on fantasy parameters. Sex guilt level had a demonstrable effect on the quantity of fantasy production and females' reports of embarrassment and vividness, whereas the type of fantasy example had more of an effect on the explicitness of fantasies and the report of sexual arousal. The two independent variables did not interact, but they affected different aspects of the sexual fantasy experience for subjects.

Specifically, sex guilt level in females resulted in HSG subjects reporting fewer, shorter, and less explicit fantasies with less variety of content and fewer themes than LSG subjects. These results supported previous research that HSG subjects were more conservative in sexual matters. The findings clearly showed that in explicitness and quantity, sexual fantasy production was under the influence of the sex guilt trait, suggesting that it may be part of a cluster of sexual behaviors governed by this trait.

Experimental fantasy cues exhibited a stronger influence than sex guilt level on explicitness and variety of content of females' fantasies. It is interesting to note that both

HSG and LSG subjects were responsive to the experimental conditions and that the predicted interactions of the effects of the stimuli conditions on HSG and LSG subjects' sexual fantasies did not occur. The speculation that HSG subjects would be more constricted and less explicit in their reported fantasies under the sexually explicit erotic condition as compared to the neutral and romantic conditions was not supported. The strong influence of situational demands on self-reported sexual fantasies for both HSG and LSG subjects suggests that clinicians and researchers need to be sensitive to the conditions under which sexual fantasy production is elicited. Sexual fantasy may be more accurately viewed as being under stimulus control rather than as a stable trait.

Response cuing may, however, place constraints on subjects' responses. The erotic fantasies that the subjects read may not have been explicit enough or varied enough in content to elicit the greatest detail or the maximum number of sexual fantasies that women have experienced. On the other hand, there may be a level of explicitness beyond which subjects would begin to censor their responses. Future research could vary the levels of sexual explicitness in an effort to determine the optimal response facilitator for fantasy production.

As proportionally more HSG females checked themes concerning being sexually dominated and being irresistible to men, it is possible that these themes indicated a reduction in responsibility for the sexual interaction, thus reducing the guilt experienced by these females. The fantasy themes preferred by LSG subjects were more often concerned with real individuals, whereas HSG subjects more often responded to themes concerning an imaginary lover.

Supporting Mosher's (1973) data, sex guilt groups did not differ significantly in degree of self-reported arousal. It is clear from these data that both groups did get at least moderately sexually aroused by sexual fantasy stimulation, and sex guilt did not seem to interfere with reporting this level of arousal. The experimental conditions did produce differences in reported arousal in the predicted direction, with more sexually explicit fantasies (i.e., erotic examples) resulting in

higher levels of arousal. This finding supports Mosher's (1973) results and suggests that sexual arousal in fantasy production seems to be a function of the degree of sexual explicitness of the stimuli rather than a function of the sex guilt trait of individuals. A study assessing actual physiological arousal rather than self-report is needed to more clearly assess the effects of sexual fantasy stimuli on arousal.

HSG subjects reported experiencing more guilt and embarrassment in response to taking part in the experiment and writing sexual fantasies than did LSG subjects, thus supporting previous findings that HSG subjects reported feeling more ashamed after exposure to sexual stimulation. They also indicated that they experienced their fantasies less vividly than did LSG subjects. The question remains whether HSG subjects, in writing fantasies, did not report as many or as explicit fantasies, because they were too embarrassed to do so rather than because they did not experience fantasies in the same way as LSG subjects. However, the more passive response of checking themes also showed the same sex guilt difference. If embarrassment were the important variable affecting fantasy production, one would have expected HSG subjects to write more under the romantic or neutral example condition, in which sexual demand characteristics were minimal. This does not appear to be the case, as HSG subjects, like LSG subjects, wrote more under the sexually explicit condition. Regarding the lower vividness ratings, a reasonable explanation is that HSG subjects, with their postulated censoring mechanisms, probably do not remember their fantasies clearly. As these ratings were initial attempts at assessing parameters of sexual fantasies via self-report, there is a definite need for research that will partial out possible causal factors and their predictive weights in the differential responding of HSG and LSG subjects.

Subjects' ratings in the three experimental conditions, in terms of guilt feelings, embarrassment, and vividness of their fantasies indicated no differential reactions to the fantasy stimuli. These results contradict those of Mosher and Greenberg (1969), who found that subjects responded with more guilt feel-

ings after sexual stimulation in the form of erotic literary passages. Since the most explicit sexual stimuli described only heterosexual intercourse, it is possible that the content of the fantasy examples was not varied enough to elicit feelings of guilt or embarrassment in the subjects. The lack of congruence of these results with the Mosher and Greenberg study suggests the need for further research to manipulate the specific parameters of explicitness and variety of content of experimental stimuli to determine the effects on self-reported guilt levels and ratings of embarrassment.

Most young adult females in this college population related at least one fantasy when asked to write their own sexual fantasies and when prompted with fantasy stimuli. Whether this stimulus situation accurately assessed the incidence of fantasies in females still needs to be determined. Future studies could ask for fantasy incidence information to be collected over a period of time in addition to the self-reported fantasies in a laboratory setting.

On the External Validity of Two Psychotherapy Analogues

Kenneth Kushner
University of Michigan

The present study investigated the similarity between two live psychotherapy analogues and real psychotherapeutic interviews. Therapists were asked to participate in two different types of analogue situations and in initial intake sessions with real clients. In both of the analogues, a recruited subject presented a real personal problem to the therapists in helping interactions. Audiotapes of the real and analogue interviews were rated on 10 dependent variables, which were different dimensions of therapist and client behaviors. Different results were obtained for each analogue. The major findings concern mean differences between the analogue and real interviews and the linear relationships between the real and analogue interviews. Additional findings, including significant interactions between the type of interview and the experience level of the therapist, are also discussed. The results are interpreted as indicating that the generalizability of the analogues is contingent on the dependent variables in question, the type of relationship to be predicted, and the experience level of the therapists. The implications that these results have for future research involving psychotherapy analogues are discussed.

The present research was inspired by the importance of analogue methodologies for process studies of psychotherapy. Since the time of the first study that used an analogue of the psychotherapeutic process (Keet, 1948), the use of psychotherapy analogues (also referred to as simplifications or simulations) has become a very popular and accepted research strategy. The types of analogues that researchers have used over the years have been both diverse and creative. They have ranged from highly artificial, non-live situations (i.e., Porter, 1950) to highly realistic live situations (i.e., Russell & Snyder, 1963). Today, the sheer number of ana-

logue studies is large enough to warrant extensive literature reviews (Heller, 1971; Munley, 1974), as well as substantive theoretical critiques (Bordin, 1965; Strong, 1971; Strupp, 1961; Thomas, 1962). It is easy to understand why analogues are often preferable to the naturalistic study of psychotherapy; they are more convenient, they afford more experimental control, and they avoid many of the ethical problems inherent in field study methodologies that require the use of real clients and therapists.

There is an underlying assumption involved in the use of analogues in psychotherapy research; namely, that the results found in the simplified situations are generalizable to the real psychotherapeutic setting that they are supposed to simulate. As Heller and Marlatt (1969) have pointed out, this is a question of the external validity of analogues. The utility of an analogue depends on the amount of confidence one can place in one's ability to extrapolate from results found in the analogue situation to the real psychotherapeutic situation to which it refers. The degree of similarity between results found in analogue and naturalistic settings is an empirical ques-

This article is based on a doctoral dissertation undertaken at the University of Michigan under the chair of Edward S. Bordin. A brief version of this report was presented at the Eighth annual meeting of the Society for Psychotherapy Research, Madison, Wisconsin, June 1977.

The author would like to thank E. S. Bordin and Erica Serlin for their thoughtful suggestions regarding the present article.

Requests for reprints should be sent to Kenneth Kushner, who is now at the Department of Family Medicine, Medical College of Ohio, C.S. # 10008, Toledo, Ohio 43699.

tion. Bordin (1965) advocated validation studies that "bridge" results found in the one setting to the other. Other authors have also suggested such empirical comparisons (e.g., Strupp, 1961). Nevertheless, as of today, validation studies can be counted on one hand (Hopke, 1955; Matarazzo, Wiens, Matarazzo, & Saslow, 1968; Roark, 1969; Sigal, Guttman, Chagoya, & Lasry, 1975; Sigal, Lasry, Guttman, Chagoya, & Pilon, 1977). In each of these five studies, the investigators found some degree of similarity between the analogue and real interviews for some of the dependent variables that they examined. However, for other dependent variables, the investigators found important differences between real and analogue situations. These results indicate that there is good reason not to accept on faith the generalizability of all results based on analogues.

The present study was undertaken to apply the principal of "empirical bridging" to two similar psychotherapy analogues. In both analogues, real therapists interviewed nonreal, or "quasi," clients in simulated initial intake sessions. In one type of analogue, the *nonstandard client analogue* (similar to Danish, D'Augelli, & Brock, 1976), each therapist interviewed a different female volunteer drawn from a subject pool. The subject was instructed to genuinely discuss a personal problem with the therapist. In the second analogue, the *standard client analogue* (similar to Carkhuff, Kratochvil, & Friel, 1968), all therapists in the sample interviewed the same female quasi-client. She was instructed to present the same real problem to each therapist and to discuss it genuinely. The therapists were instructed to conduct both types of analogues as if they were real initial intake interviews. Thus, the two types of analogues were identical, except for the fact that one interviewee was used in the standard client analogue and multiple interviewees were used in the nonstandard client analogue.

Method

Design

The present study contained a within-subjects design, in that each therapist participated in the standard client analogue, the nonstandard client analogue, and the real initial intake interviews. All

interviewees were female, and the order of presentation of the two analogues was balanced in the sample. This design allowed for direct comparison of the process of each analogue to the real therapy interviews.

Subjects and Procedure

Therapists were recruited from four campus mental health agencies. Thirty-one therapists volunteered to participate in the study. The minimum qualifications for therapists to be included in the data analysis was having completed at least one real and one analogue interview. As a result, 23 therapists were included in the data. Of these, 15 therapists participated in both analogues and two real interviews, 7 therapists participated in both analogues but were able to record only one real intake interview, and 1 therapist participated in only the nonstandard client analogue but recorded two real initial intake interviews. The remaining 8 therapists, those who volunteered to participate but who did not record at least one real intake session, all reported that they were unable to obtain appropriate intake interviews. The therapists who participated in the study were a diversified group, as shown by an even sex distribution and wide ranges of age, experience level, and theoretical orientation.

The clients for the *real therapy* interviews were selected by the therapists. Each therapist was asked to tape record the first two real intake sessions that met the following criteria: (a) The client had to be female; (b) the presenting problem had to be emotional rather than solely educational or vocational in nature; (c) it had to last at least 30 minutes; and (d) the client had to agree to participate in the research.

The subjects in the nonstandard client analogue interviews were females recruited by phone from a paid subject pool. They were told that the study would entail having an interview with a therapist in which they would talk genuinely about a real personal concern or problem. The only prerequisite was that they were not currently involved in counseling or psychotherapy.

The client for the *standard client analogue* interview was a 21-year-old senior undergraduate psychology major. She was instructed to choose a real personal problem, and other than presenting it in the same words to each therapist, she was asked to discuss it genuinely and spontaneously in each interview. Thus, her instructional set was essentially the same as that of the nonstandard clients. The standard presenting problem that she chose concerned her ambivalence about her relationship with her boyfriend, especially whether she should move to the east coast when she graduated instead of staying in the midwest to be near him. She described the problem on the information sheets as follows for each interview: "Confusion about various things—i.e., boyfriend and where I go at the end of the year—how can I make some important decisions related to above—do I think too much about it, etc."

In designing the two analogues, the attempt was made to create situations that differed from the real therapy interviews only by virtue of the fact that the analogue subjects were actively recruited to discuss real problems, whereas the real therapy clients were self-motivated to seek help for their problems. For this reason, all interviews (analogue and real) were conducted in the therapists' own offices. In addition, the analogue subjects, as well as the real clients, presented to the therapist a face sheet providing both demographic information and their presenting problem(s). In both analogue interviews, the instructional set was designed to parallel the demand characteristics of a real therapy interview; the subjects were requested to present real problems, and the therapists were asked to conduct the interviews as if they were actual initial intakes. The therapists were aware of which real clients were being taped for research purposes. They were also informed that the analogue subjects were experimental subjects. However, they were not told that there were any differences between the two analogue interviews. Specifically, an attempt was made to keep the therapists blind to the fact that one of the subjects was being seen by other therapists. During debriefing, eight therapists reported knowledge or suspicion that a standard client was used.

It is worth noting that I judged the real and analogue situations to be equivalent in terms of one more important characteristic—presenting problem. The presenting problems of the real and nonstandard clients mostly centered on interpersonal and/or academic concerns. Difficulties with parents, boyfriends, or schoolwork were typical examples. In light of this fact, the standard client's presenting complaint was representative of the type of problems presented by the other subjects. It is also worth noting that the mean age of the real clients was 22.3 and that of the nonstandard clients was 19.9. This difference was significant, $t(59) = 3.33$, $p < .01$. Although the attempt was made to keep the real clients, standard client, and nonstandard client interviews equivalent in length by asking the participants to keep them between $\frac{1}{2}$ and 1 hour, their mean lengths were 49 min 3 sec, 40 min 22 sec, and 42 min 49 sec, respectively. Only the contrast between the real client and standard client analogue interviews was significant ($p < .05$).

Dependent Variables

The audiotape recordings of the real client, standard client, and nonstandard client analogue interviews were rated for the following 10 dependent variables that were selected due to their relevance to psychotherapy research in general and analogue research specifically: accurate empathy, nonpossessive warmth, genuineness (all after Truax & Carkhuff, 1967), ambiguity (after Osburn, 1951), question-to-statement ratio (Q/S; after Ornston, Cicchetti, Levine, & Fierman, 1968), mean duration of therapist utterance (TUL), mean duration of client utterance (CUL), percentage of client talk time (C%), percent-

age of therapist talk time (T%), and percentage of silence (S%; all after Matarazzo et al., 1968).

For accurate empathy, nonpossessive warmth, genuineness, and ambiguity, the ratings were done on four excerpts per tape, each approximately 4 minutes in duration. This yielded four scores per interview. A mean score for each variable was then calculated for each interview. Unless stated otherwise, it was these mean scores that were used in the data analysis. The remaining dependent variables—Q/S, TUL, CUL, C%, T%, and S%—were rated for the entire tape by a hand-held stopwatch, yielding one overall score per interview per variable. For one therapist whose data was included in the analysis, the excerpts were inaudible, and the raters were unable to rate her interviews for empathy, warmth, genuineness, and ambiguity. However, they were able to rate the original tapes for the remaining variables.

Raters and Rater Reliability

The raters were six undergraduate psychology majors. Three of them rated the interviews for accurate empathy, nonpossessive warmth, and genuineness. The other three rated them for the remaining dependent variables. Both groups of raters were given extensive training and practice in the use of the scales by me, and each group had to demonstrate a high degree of interrater reliability before the actual rating began. For both groups of raters, prerating reliability was determined on the basis of their scores on 11 4-minute excerpts taken from therapy sessions that were not in the present sample. In addition to the prerating reliabilities, each group of raters rated the same 11 excerpts spread over the actual ratings. These scores allowed me to determine the "drift" in reliability that might have occurred in the process of rating. In determining reliability, correlation coefficients were computed for each of the three pairs of raters within each group, and a mean of these three coefficients was then calculated. Instead of calculating the coefficient for the Q/S ratio, separate coefficients were calculated for the number of questions and the number statements.

The prerating reliabilities were uniformly high, ranging from correlations of .75 for warmth to .99 for CUL. The drift rating coefficients were also high for all dependent variables except empathy and warmth, which were .01 and .53, respectively. Since this raises questions about the value of the ratings for empathy and warmth, the results pertaining to these two variables have been omitted from the following presentation. Correlations for all prerating and drift rating reliabilities can be found in Kushner (1977).

Results

Mean Differences Between Analogue and Real Interviews and Effects of Therapist Experience Level

To investigate whether there were mean differences between the real and analogue

Table 1
Cell Means for Conditions Main Effect for Both Analogues Versus Real Interviews

Variable	Condition			<i>F</i>	<i>df</i>
	Real	Standard	Nonstandard		
Genuineness	2.31	2.36	2.19	1.23	2,28
Ambiguity ^a	13.98	19.22	15.75	2.61	2,28
CUL (in sec)	20.51	10.64	19.78	5.67*	2,32

*** $p < .001$.

interviews, an analysis of variance of the form Conditions \times Experience \times Therapists was calculated for each dependent variable. There were three levels of the conditions factor (real, standard, and nonstandard).¹ Experience was included as a factor due to the large range of clinical experience in the sample of therapists (0–20 years) and the fact that it was wondered whether the analogues would reflect differences between less experienced and more experienced therapists. Accordingly, the sample was split at the median into a group of less experienced (0–3 years) and more experienced (5+ years) therapists. This yielded two levels of the experience factor. Thus, therapists were nested within experience, and conditions were crossed with both experience and therapists. Several therapists had to be randomly discarded in order to balance the cells, resulting in 16 therapists in those analyses conducted on genuineness and ambiguity and 18 in those conducted on the remaining variables. For those variables that were bounded ratios (C%, T%, and S%), the analyses were conducted on the arc-sin transformations of the raw scores.

The cell means and *F* ratios of the conditions main effect are displayed in Table 1.² To determine whether the real interviews differed from either analogue, Dunnett's method

of testing all cell means against one control (Winer, 1971) was used to test the significance of the two pairwise contrasts of interest: between the real and standard client interview conditions and between the real and nonstandard client interview conditions. The results of Dunnett's test for these variables that had significant overall *F* ratios appear in Table 1. As can be seen, the conditions main effect was significant for CUL and C%. For these two client variables, the contrasts between the real client and standard client conditions were significant, revealing that the standard client had shorter mean durations of utterance length and talked for smaller percentages of the sessions than did the real

¹ In all analyses of variance, the scores of the first real interviews were used for those therapists who had recorded two real initial intake sessions. Prior to conducting the analyses, *t* tests had shown that there were no significant differences between the first and second real interviews.

² Actually the analyses for genuineness and ambiguity were conducted as repeated measures analyses of variance. This was because four ratings of those variables were made from each tape, one from each excerpt. Thus, the design for these variables was Conditions \times Experience \times Therapists \times Replicates; with 3, 2, 8, and 4 levels of each factor, respectively. (For a further treatment of this, see Kushner, 1977.)

Table 2
Cell Means for the Experience Main Effect

significance.³ In no instance was the contrast between the real client and the non-standard client interviews significant.

Table 2 displays the cell means and *F* ratios for the experience main effects. As can be seen, there were significant differences between the less experienced and more experienced therapists for the following dependent variables: ambiguity, CUL, Q/S, C%, and T%. Significant Experience \times Conditions interactions were found for three dependent variables ambiguity, C%, and T%. The cell means and *F* ratios of these significant interactions are displayed in Table 3. The same two patterns are reflected in the cell means of all three of those interactions. The first pattern is that the differences between the less and

³ A second set of analyses of variance, based on a larger sample size, did in fact reveal a significant difference between the real and standard client conditions for T%. This was when the analyses were calculated without the experience factor (Conditions \times Experience). This enabled the inclusion of the data of three more therapists. (They had originally been disregarded in order to balance the cells for the previous series of analyses.) Similarly, this second set of analyses revealed a significant conditions main effect for S%, $F(2, 42) = 3.38$, $p < .05$, and a significant contrast between the real and standard client analogue conditions for that variable ($p < .05$). These results, and the summaries of all the analyses, are discussed in Kushner (1977).

more experienced therapists that were evident in the experience main effect were found in the real client and nonstandard client interviews but not in the standard client interviews. Rather, the cell means for the standard client interviews were almost identical for the less experienced and more experienced therapists.

The second pattern that was reflected in the cell means of the significant Experience \times Conditions interactions for ambiguity, C%, and T% is that there was much greater range in the cell means across conditions for the interviews conducted by the less experienced therapists than there were for the more experienced therapists. For the less experienced therapists, the disparities between the means of the real client and standard client conditions were the most pronounced. For the more experienced therapists, the cell means of all three conditions seemed roughly equivalent. Apparently, the former therapists were more influenced by the differences in the type of subjects that they were interviewing than were the latter therapists.

Linear Relationships Between the Real and Analogue Interviews

The linear relationships between the real and analogue interviews address the ability to make predictions regarding the relative performance of specific therapists in real therapy on the basis of his/her performance in an analogue. This was investigated via two sets of correlations. One was based on the same therapists' scores in the real interviews and in the standard client analogue; the other was based on the same therapists' scores in the real interviews and in the nonstandard client analogues. The correlations were calculated using the mean of the first and second real interviews for those therapists who participated in two initial intake sessions. The results of the correlations are summarized in Table 4. An analogue can be said to be a predictor of real therapy behavior if the coefficient is positive and significant. The standard client analogue was a predictor for three dependent variables: genuineness, CUL, and Q/S. The nonstandard client analogue

Table 4
Correlations of Scores of Same Therapist's Real Interviews Versus Each Analogue Interview

Variable	Comparison			
	Real ^a vs. standard		Real ^a vs. nonstandard	
	<i>r</i>	<i>df</i>	<i>r</i>	<i>df</i>
Genuineness	.77*	19	.20	20
Ambiguity	.27	19	.10	20

Note. CUL = mean duration of client utterance; TUL = mean duration of therapist utterance; Q/S = question to statement ratio; C% = percentage of client talk time; T% = percentage of therapist talk time; S% = percentage of silence.

^a Means of raw scores of first and second initial interviews were used for those therapists who submitted two real interviews.

* $p < .05$.

** $p < .01$.

was a predictor of real therapy behavior only for Q/S.

A supplemental set of analyses revealed an interesting and somewhat surprising result. The correlations were calculated between the first and second real interviews for those therapists who recorded two initial intake sessions. The coefficients were quite low, with none of them attaining statistical significance. (See Kushner, 1977, for coefficients.) This indicates that behavior in one initial intake session did not adequately predict behavior in a second initial intake that the same therapist conducted with another client. It should be noted that the correlations between the two real interviews did not differ statistically from either the real and standard client analogues or the real and nonstandard client analogues. Thus it cannot be concluded that a second real interview is a better or worse predictor of a therapist's real interview than either the standard client or nonstandard client analogue.

Table 5

Variances of Dependent Variables with F Tests for Pairwise Comparisons Against Standard Client Condition

Variable	Variance			Standard vs. real		Standard vs. nonstandard

* $p < .01$.

Differences in Variance Between the Standard Client and Other Interview Conditions

The last set of analyses does not relate to the generalizability of the analogues, but rather to the rationale behind the use of a standard client. The single interviewee should theoretically provide a more constant stimulus than multiple interviewees. Therefore, there should be less variance for the dependent measures in the standard client condition than in the real client or nonstandard client conditions. This issue was addressed by calculating the variance in each condition and then conducting two *F* tests—one contrasting the dependent measures for the standard client analogue and real interviews and the other contrasting the standard client and the nonstandard client interviews. The variables and *F* tests are shown in Table 5. The *F*s were significant only for CUL and C%, showing that there was considerably less variance in client behavior for these variables in the standard client interviews than in either the real client or nonstandard client interviews.

Discussion

Several main findings regarding the similarity between the analogue and real interviews were obtained in the present study. These will be discussed with reference to

their implications regarding the future use of the analogues: First, there were no mean differences between the real client interviews and the nonstandard client analogues for any of the eight dependent variables. However, there were significant mean differences between the real client interviews and the standard client analogues for mean duration of client utterance and mean duration of therapist utterance. These mean differences indicate that the levels of functioning of the standard client would not be predictive of the magnitude of the means of the real therapy clients. The significant Conditions \times Experience interactions for ambiguity, C%, and T%, which showed greater ranges in the cell means across conditions for the less, but not the more, experienced therapists indicate that there were mean differences between the real interviews and the standard client analogue for the former therapists only. These significant Conditions \times Experience interactions also indicate that the standard client analogue did not reflect the mean differences for ambiguity, C%, and T% found in the real interviews between the less and more experienced therapists, but the nonstandard client analogue would have predicted those differences. For the remaining dependent variables, the lack of significant Conditions \times Experience interactions indicates the abil-

ity of both analogues to reflect true differences (or lack of differences) between interviews conducted by less experienced and more experienced therapists.

The correlations between the real and analogue interviews addressed the ability to predict the relative performance of individual therapists in real therapy on the basis of their behavior in the analogues. The analogues were rather disappointing as predictors. The standard client analogue was found to be a predictor of genuineness, CUL, and Q/S. The nonstandard client analogue was found to be a predictor for Q/S only. Although the low correlations between the two real interviews might be attributable to the small sample size on which they based ($ns = 14$ and 16), other authors (Beutler, Neville, & Workman, 1973) have reported low correlations between real interviews of the same therapists. This implies that therapists might be highly variable from session to session.

It should be clear from the above summary that the external validity of an analogue is not an all-or-nothing property; rather, the utility of an analogue as a predictor of real therapy behavior may be dependent on several factors, such as (a) the dependent variables in question, (b) the type of relationship that one would want to predict (i.e., mean differences between groups of therapists or the relative performance of individual therapists), and (c) the experience of the therapists participating in the analogue. It should be noted that the present study cannot be seen as a blanket validation of the use of the two analogues. Rather, conclusions about the validity of any analogue should be specific, in that they should define the variables and conditions for which it is concluded to be predictive of real therapy behaviors. The onus is on the researcher to empirically establish continuity of style between the analogue and real therapy, rather than assuming it to be there for all variables.

It is obvious that the results obtained for the standard client in the present study may have been ideosyncratic of her particular interviewing style (characterized by relatively less verbal behavior and shorter interview lengths) and thus may not be general-

izable to other standard clients. A study that contrasted the interviews of several standard clients to real interviews with the same therapists would address this issue.

In addition to the study proposed above, the present study has several other implications for future research: (a) It adds more evidence that results found in analogues may not be generalizable to real therapy behaviors. Therefore, more validation studies should be undertaken for other analogue situations. (b) Interpretation of results based on nonvalidated analogues should be tentative in nature. (c) Naturalistic studies appear to be largely preferable to analogue studies from the standpoint of rigor. (d) The consistency of therapists in real interviews should continue to be studied. If it is true that therapists are highly variable from interview to interview, then sampling several interviews by the same therapist would be a more valid procedure for future research than merely sampling one interview.

Are Special Norms for Minorities Needed? Development of an MMPI *F* Scale for Blacks

Malcolm D. Gynther
Auburn University

David Lachar
Lafayette Clinic
Detroit, Michigan

W. Grant Dahlstrom
University of North Carolina

As part of a large-scale investigation of the need for special Minnesota Multiphasic Personality Inventory (MMPI) norms for black adult American test subjects, 882 normal black adults from Alabama, Michigan, and North Carolina were tested. Item analyses of these protocols revealed 33 items that met the 10% or less endorsement criterion used to develop the MMPI *F* scale. Comparisons were made between white and black endorsements of the items on this new scale, items of the standard *F* scale, and additional items in the MMPI pool that met the 10% criterion but were not included in the original *F* scale. White endorsement patterns agreed with the blacks' *F* scale, but black endorsement patterns agreed with only one third of the standard *F*-scale items. Further, black adults showed comparable levels of infrequency on only 6 of the 38 supplementary *F* items. Although these results do not necessarily indicate that special norms for the clinical scales are necessary, the amount of difference between responses of blacks and whites to rarely endorsed items suggests that for blacks, this new scale may be a more accurate measure of correlates associated with endorsement of deviant items than the standard *F* scale.

The *F* scale of the Minnesota Multiphasic Personality Inventory (MMPI) was proposed as one of the validity indicators by the test's authors, Hathaway and McKinley (1951). The 64 items comprising this scale were selected in part on the basis of the frequency of endorsement and in part on the basis of diversity of item content. That is, the items chosen were answered in the scored direction by 10% or less of the subjects in the Minnesota normative adult samples, and they covered a wide range of topics, with only a few items referring to any one area of behavior or experience. The item tallies used

to identify potential *F*-scale items came from an early subsample of the Minnesota normal subjects (111 men and 118 women); subsequent analyses reported in Hathaway and Briggs (1957) and Dahlstrom, Welsh, and Dahlstrom (1975) indicate that on the more complete data of the Minnesota samples, 3 of the 64 items do not meet the 10% or below criterion, and 1 additional item satisfies this criterion only for females. In addition, there are 38 items that could have been included in the *F* scale, but they were excluded by the test's authors even though they were endorsed by 10% or less of the revised Minnesota normal adult group.

High scores on this scale (typically $F > 16$) signified that the profile was invalid due to the subject's carelessness or lack of comprehension. Other reasons for obtaining elevated scores were recognized early in the development of the inventory. Meehl and Hathaway (1946) stated that schizoid subjects

This investigation was supported in part by National Institute on Drug Abuse Grant 7H81 DA-01879-01. The authors wish to thank James L. Grisell, Michael Butkus, Roger Gudobba, and Paul Sherwood for assistance in data analysis.

Requests for reprints should be sent to Malcolm D. Gynther, Department of Psychology, Auburn University, Auburn, Alabama 36830.

and subjects who apparently wished to put themselves in a bad light also obtained high scores on this scale. Dahlstrom, Welsh, and Dahlstrom (1972) have described several other possible reasons for high scores, such as random responding, answering true to all items, cyclical alternations of true and false answers, a cry for help or pleading for special attention, a bilingual background with English as a second language, visual impairment, and acute psychotic disorganization.

Research has shown personological and psychopathological correlates of elevated MMPI *F* scores obtained by whites. Among persons relatively free of serious problems in living, the Institute of Personality Assessment and Research studies (Gough, McKee, & Yandell, Note 1) characterized those with moderately high *F* scale scores as moody, restless, dissatisfied, and opinionated. Carson (1969) has suggested that *T* scores in the range of 65 to 80 frequently appear in sullen, rebellious personalities of the schizoid, antisocial, or Bohemian type. High MMPI *F* scores obtained from court cases referred for diagnostic evaluation have been shown to be related to a diagnosis of psychopathy (Gynther, 1961; Gynther & Shimkunas, 1965), as well as to the commission of serious sex crimes (Gynther, 1962). Elevated *F* scores obtained from psychiatric patients appear to be associated with withdrawal, poor judgment, short attention span, delusions, and hallucinations (Gynther, Altman, & Warbin, 1973). Other correlates of moderate to high MMPI *F* scores can be found in Lachar (1974), Duckworth and Duckworth (1975), and Graham (1977). Dahlstrom et al. (1975) have summarized the research (provided that the sources of protocol invalidity mentioned earlier can be dismissed) as indicating that "the degree of emotional disturbance in the individual can be judged with reasonable accuracy from the elevation of the *F* scale" (p. 31).

It is interesting to note, in this context, that black subjects typically obtain higher scores on the *F* scale of the MMPI than white subjects. There have been 10 studies to date comparing noninstitutionalized blacks and whites on the MMPI. In all but 1 of

these studies (several of which attempted to control for social class), blacks obtained significantly higher scores than whites on this scale. Fifteen studies have compared black and white institutionalized subjects (i.e., psychiatric inpatients and outpatients, prisoners, etc.) on the validity and clinical scales. In 8 of the 15 comparisons, blacks got significantly higher *F* scores than whites. Although evidence of racial bias is most consistent in normal samples, there was no instance in any of the 25 studies (cf. Gynther, 1972; Gynther, Note 2) in which the scores of whites on this scale significantly exceeded the scores of blacks.¹

Should these results be taken as indicating that black subjects have more difficulties in completing the MMPI validly due to poor reading skills, inability to follow directions, confusion, or other sources of profile invalidity, or that black subjects are more rebellious, nonconforming, or emotionally disturbed than whites? That is, should the white-derived descriptors be applied to blacks? Only two studies have addressed this question. Gynther et al. (1973) found *no* correlates associated with $F \geq 26$ MMPIs produced by black psychiatric patients, although a meaningful cluster of correlates for this code type was established for white psychiatric patients. More recently, Hedlund (1977) showed that MMPI *F* scores of black psychiatric patients are positively associated with scores of items assessing "disorientation," "confusion," "delusions," and other behaviors suggesting psychosis. Hedlund (1977) pointed out that as far as Scale *D* and perhaps Scale *F* correlates were concerned, "most of the relationships were similar for blacks and whites but that smaller *N*s for the black samples precluded cross-validated statistical significances" (p. 744). Hedlund, however, con-

¹ Two additional black-white comparisons have been located. One used male misdemeanor offenders as subjects, and the other used male drug abusers. Blacks obtained nonsignificantly higher *F* scores than whites in the former study (McCreary & Padilla, 1977), but they obtained significantly lower *F* scores than whites in the other study (Penk & Robinowitz, 1974). This latter finding is unique among the 27 studies examined.

cluded that "very few of the significant white relationships were validated for blacks" (p. 744). In what appears to be a highly pertinent observation, Dahlstrom et al. (1972) stated that

an important part of interpreting test items seems to be an ability to share the common cultural framework of the derivational samples studied by the test authors. Many subjects lacking this essential experiential core will show their atypical attributions and self-labeling by endorsing *F*-scale items in an unusual way. (p. 117)

This study proposes to determine which of the 566 MMPI items were rarely (i.e., 10% or less) endorsed by a large sample of normal black adults. These items are then compared with *F*-scale items (and the 38 other rarely endorsed items mentioned earlier) that were derived from Minnesota whites using the same criterion. If there is a large amount of overlap between the two sets of items, support would be provided for the continued use (and general interpretation) of the MMPI *F* scale for blacks as well as for whites. If, on the other hand, the two *F* scales are quite different, it would be suggested that use of the original *F* scale with blacks leads to inaccurate and inappropriate representations of such subjects. These analyses were carried out as part of a large-scale investigation of the need for separate norms for ethnic minorities on the standard MMPI scales. This project is briefly described below, but a more complete report is in preparation (Lachar, Gynther, & Dahlstrom, Note 3).

Method

Subjects were obtained from Alabama, Michigan, and North Carolina to derive norms for blacks on the validity, clinical, and other frequently used scales of the MMPI (Lachar et al., Note 3). Major sources were church groups and social clubs, which were paid \$5 per participant. Black faculty and graduate students administered the inventory, usually to 5-10 persons at a time, and also asked subjects to supply face-sheet information on a form devised for that purpose. Confidentiality was assured by the use of code numbers rather than names. Total sample size was 882, 321 males and 561 females. Age varied from 18 to 65, with means 36.0 for males and 34.1 for females. Approximately 15% of the subjects had not completed high school, 27% were high school graduates, 26%

had some college, 18% had graduated from college, and 14% had some postgraduate work. Approximately two thirds of the subjects had attended segregated schools. Slightly over 50% of the sample was married, 30% were single, and the remainder were widowed, divorced, or separated. In terms of employment status, about 15% were unskilled, unemployed, or on welfare; about 21% were semi-skilled, approximately 13% were classified as skilled manual, nearly 18% were clerical workers, salespersons, or technicians; about 8% were administrative or minor professionals, 22% were managers or lesser professionals; and 3% were executives or major professionals. Mean annual family income for the males was \$14,756 and for the females was \$12,296. In response to questions concerning history of treatment for emotional (nervous) condition or time served in prison, 3.7% of the males responded affirmatively to the former question and 2.1% to the latter question. The comparable figures for females were 6.2% and .7%.

Comparison of sample demographic characteristics with contemporary census data (U.S. Bureau of the Census, 1976, 1977) suggests that the distribution of age, marital status, and percentage of unemployment is comparable to national estimates of blacks 18 years and older. Examination of other variables indicates that our sample had less frequently failed to complete high school (17% vs. 50%) and had attained more college experience (50% vs. 19%). A correlate of this greater education attainment in our sample was, in comparison to census data, less unskilled and more managerial and professional vocations, as well as a higher mean yearly family income. This substantially middle-class sample was the result of sample selection methodology that for the most part included socially active and community-oriented individuals. These biases in our sample were generally of the kind that would make our estimates of the presence of race-related differences at the item level conservative rather than extreme; that is, a more representative, less educated group of subjects would presumably respond in an even more discrepant manner.

Endorsement rates of all MMPI items were examined to locate those items endorsed, either positively or negatively, by 10% or less of the black sample. One could have analyzed male and female data separately or could have applied the 10% criterion to all 882 subjects regardless of sex. The former procedure was used to develop the MMPI *F* scale with the 111 males and 118 female protocols then available. If one looks at the endorsement data for the larger, revised Minnesota adult group (Dahlstrom et al., 1975, Appendix A), it will be noted that both males and females met the 10% or less criterion for 47 of the 64 *F* items. With regard to the remaining items, males exceeded the criterion on 12 items, females on 4 items, and males and females on 1 item. However, if the responses of both sexes are combined, the criterion was met for 60 of the 64 *F* items. Since the MMPI *F* scale

can best be characterized as consisting of items rarely endorsed in the scored direction by the *whole* sample (despite the procedure originally used), we felt that a black *F* scale to be comparable should also be determined by responses of the entire sample. However, if marked differences between the sexes on scale means (and standard deviations) were found, different raw-score to *T*-score conversions would be considered.

Comparisons were made between blacks and whites on the items that met the 10% or less criterion for blacks, items on the *F* scale that met the criterion, items on the *F* scale that did not meet the criterion, and items not on the *F* scale that met the criterion for the revised white adult group.

Results and Discussion

Examination of the endorsement rates of the black sample disclosed 33 items that met the 10% or less criterion. Twenty of these items are keyed true (10, 14, 23, 48, 49, 85, 104, 123, 151, 197, 210, 211, 227, 246, 291, 324, 339, 365, 393, 565), and 13 are keyed false (2, 75, 88, 90, 113, 177, 196, 220, 257, 258, 272, 276, 285). Although a number of statements that would be rated "obvious" for presence of psychopathology if answered true can still be found in this *F* scale for blacks (e.g., "I believe I am being followed," "Someone has been trying to poison me," and "Everything tastes the same."), it is noteworthy that a number of old standbys have dropped out (e.g., "My soul sometimes leaves my body," "I see things and animals around me that others do not see," and "I commonly hear voices without knowing where they come from.").

The scores of the black normative group on this scale can be summarized as follows: for males, $M = 2.97$, $SD = 4.02$, and range = 0-20; for females, $M = 2.72$, $SD = 3.52$, and range = 0-22. These values for males and females are sufficiently similar to make separate raw-score to *T*-score conversions unnecessary. A raw score of 3 can be considered equivalent to a *T* score of 50; a raw score of 7, equivalent to a *T* score of 60; and a raw score of 11, equivalent to a *T* score of 70. An additional cohort of subjects, black psychiatric patients evaluated at Lafayette Clinic, obtained the following scores: for 197 males (M age = 29.04; M education = 11.93), $M = 5.09$, $SD = 5.16$, and range =

0-33; for 280 females (M age = 31.17; M education = 12.31), $M = 5.92$, $SD = 4.95$, and range = 0-33. The distributions obtained by normal and psychiatric black subjects range more widely over this scale than do distributions of whites' scores over the standard *F* scale. It seems clear that some test-taking differences may still be reflected in the way that black subjects describe themselves, even on this selected set of items.

Relations among selected demographic variables, standard *F*-scale, and black *F*-scale scores were examined. Mean black *F*-scale *T* scores for various demographic groupings obtained a limited range of 47 to 56, whereas standard *F*-scale *T* scores ranged from 53 to 75. Analyses of variance revealed that scores on both scales were significantly related to age, education, and job classification of head of household. Standard *F*-scale *T* scores, for example, averaged less than 60 for those of our normal black subjects who were either 35 or older, had attained a college education, had managerial or professional status, or lived in a household headed by a managerial or professional person. If, on the other hand, the subject was 18-24 years of age, had less than 12 years of education, was unskilled or unemployed, or lived in a household with an unskilled or unemployed breadwinner, mean *F*-scale *T* scores ranged from 67 to 75.

Table 1 summarizes the endorsement rates of blacks and whites on the *F* items for blacks that were enumerated earlier in this section, the MMPI *F* items, and the 38 items that met the criterion for inclusion in the *F* scale but were not so classified by the test authors. Examination of these data shows that whites and blacks responded quite similarly to the 33 items that comprise the *F* scale for blacks. Although these figures suggest a high degree of overlap between responses to the *F* scale of blacks and responses to a substantial proportion of what appears to be the MMPI *F* scale, it should be noted that 6 of the 28 items do not appear on the original *F* scale. Comparison of the responses of blacks and whites to the standard 64-item scale shows considerable disagreement. Blacks exceeded the cutoff on 65.6%

Table 1
Number of Blacks' F Scale, MMPI F Scale, and Supplementary F Items Endorsed Below and Above the 10% Level by Minnesota White Normal Adults and Black Adult Subjects in the New Normative Sample

Group	F items					
	Blacks (<i>n</i> = 33)		MMPI (<i>n</i> = 64)		Supplementary (<i>n</i> = 38)	
	≤10%	>10%	≤10%	>10%	≤10%	>10%
Blacks	33	0	22	42	6	32
Whites*	28	4	60	4	38	0

Note. MMPI = Minnesota Multiphasic Personality Inventory.

*One of the 33 items (i.e., 565) cannot be assigned to either category, since the exact percentage of true responses is not available for the revised Minnesota white adult group.

of the items. Excluding the 4 items that did not meet the criterion for whites, there was agreement on 36.7% of the items. Performance on the supplementary *F* items was even more disparate; blacks and whites agreed, in the sense of both meeting the 10% or less criterion, on only 15.8% of the items. Although whites were in agreement with 85% of the items designated as *F* for blacks, blacks concurred with only 28 out of the 98 items that meet the 10% criterion for whites. Actual percentage differences between blacks and whites on the 70 items responded differently ranged up to 30. The mean percentage of difference for these items was 10.

There are many reasons for these differences. One explanation appears to be intrinsic to the original derivation of the MMPI *F* scale. The rarity of the deviant responses ranged from 0% (every white female responded true to Item 177, "My mother was a good woman") to 10% (and in four cases to above 10%, as we have indicated). One might ask if the endorsement rates of blacks agreed or disagreed with those of whites as a function of degree of rarity. Perhaps the responses of blacks to these items only differed from those that were "marginal" members of the category. To test this hypothesis, the *F* items were divided into two categories, one with a 6% or more endorsement rate (*n* = 34) and the other with a 5% or less endorsement rate (*n* = 30). Of the 22 items that blacks endorsed 10% or less, 18 fell in the 5% or less white endorsement category,

whereas 30 of the 42 items that blacks endorsed more than 10% fell in the 6% or more white endorsement category, $\chi^2(1) = 16.5$, $p < .01$. It would be simplistic (and not true) to say that blacks only disagreed with marginal *F* items, but the trend is definitely in that direction.

These findings can be viewed as what one might expect from a validity generalization study, that is, the typical reduction in number of significant items, descriptors, or correlates when original relationships are examined via a new sample. Would *any* new sample lead to similar results? Might not comparison of whites currently residing in Alabama, Michigan, and North Carolina with the vintage Minnesota whites lead to results similar to those found here? This is an empirical question, and we hope someone will collect the data to answer it. Our speculation, however, is that a present-day group of whites will not differ as much from the Minnesota norm group as our blacks did, because mean MMPI *F* scores of white normals have not changed much from the established norms over the years, whereas blacks' mean *F* scores have repeatedly been found to be at least as high and often substantially higher than the norms.

Since the degree of overlap between blacks' and whites' endorsement rates of MMPI *F*-scale items was only about 35%, it would appear that the newly derived *F* scale may be, especially for middle-class members of this minority group, a better measure of

deviant responding (and perhaps nonconformity?) than the standard scale. Whether blacks who obtain elevated scores on this new *F* scale are as moody, opinionated, rebellious, and emotionally disturbed as whites who obtain elevated scores on the standard *F* scale have been shown to be must await further research.

Parental Personality Factors in Child Abuse

John J. Spinetta
San Diego State University

In an attempt to demonstrate that abusing parents differ from nonabusing parents in personality variables, the Michigan Screening Profile of Parenting was administered to six groups of mothers: (a) adjudicated abusers, (b) spouses of adjudicated abusers, (c) mothers convicted of child neglect, (d) nonabusing mothers from a college student population, (e) nonabusing mothers from a middle socioeconomic level, and (f) nonabusing mothers from a lower socioeconomic level. Major differences occurred when comparison was made of one or more of the first three groups with one of the latter three groups. The groups differed significantly on six factor-analyzed cluster categories: (a) relationship to one's own parents, (b) tendency to becoming upset and angry, (c) tendency toward isolation and loneliness, (d) expectations of one's own children, (e) inability to separate parental and child feelings, and (f) fear of external threat and control. In all of the cases, the first three groups scored at levels of higher risk than did the latter three groups, whereas the abusers scored at the highest risk levels throughout. It is suggested that a therapist who helps a parent develop the ability to maintain equanimity under stress, by helping reduce deviations from the norm in characteristics related to abuse potential, is ultimately helping to reduce actual abusive behavior.

With the growing emphasis in the literature on the fact that the causes of child abuse are multiple and interactive, many therapists who deal with parental personality and attitudinal variables are made to feel as if they are engaging in a futile effort (D'Agostino, 1975; Smith, 1975). Although many new and exciting identification and treatment programs for child abuse abound throughout the country (National Center on Child Abuse and Neglect, 1975, 1976), very little encouragement has been given to the therapist who does not have easy access to the new interdisciplinary treatment programs and who, in many instances, remains the

sole therapeutic agent for a particular set of families (Steele, 1975). The problem is viewed as sufficiently complex that an individual therapist who deals solely with parental attitudes is often discouraged. It is the purpose of this study to demonstrate that parental personality and attitude are important factors in the etiology of child abuse. Such a demonstration can give hope to the therapist that efforts in dealing with the parental personality are aimed in a profitable direction and that he or she can be effective in reducing potential for abuse.

It is not my intent to suggest that factors of parental background or inadequacy are the sole determinants of child abuse. The fact is that the causes of child abuse are multiple and interactive; there is no single type of child abuser or a single causative factor as sufficient explanation of abuse (Spinetta & Rigler, 1972). Emphasis on parental personality is in no way meant to detract from these other factors. Rather, it is suggested that helping the parent to develop the ability to maintain equanimity

The author wishes to thank Richard Bourke, Esther Cardall, and Don King of the Department of Public Welfare, County of San Diego, and their social service staffs for their assistance in the administration of the questionnaires and Ruth Reinman and Richard Sprigle for their help in the coordination and analysis of the data.

Requests for reprints should be sent to John J. Spinetta, Department of Psychology, San Diego State University, San Diego, California 92182.

under stress is directly related to situational variables, and it can be of central value in the rehabilitative or preventive process.

It is in the broader context of situational variables that I ask the question, Why is it that the majority of parents do not abuse their children? Although in the socially and economically deprived segments of the population there is generally a higher degree of the kinds of stress factors found in abusing families, the great majority of deprived families do not abuse their children. Why is it that most deprived families do not engage in child abuse, though they are subject to the same economic and social stresses as those families who do abuse their children? Is there an actual difference between the types of stresses encountered by abusing parents and nonabusing parents within the same socioeconomic level (Gil, 1970, 1976), or is the difference in the parents' manner of approaching the stress situation (Kent, 1976; Smith, 1975; Spinetta & Rigler, 1972; Young, 1976)? I hold the latter position. When one takes into account the fact that some well-to-do and middle-class families also engage in child abuse, then one must look for the causes of child abuse beyond mere socioeconomic stress. The problem of etiology remains insoluble at the demographic level alone.

The present study is an attempt to demonstrate that however one might explain the particular circumstances that helped shape the parents' personality, abusing parents differ from nonabusing parents in attitudinal and personality variables.

Method

Instrument

In 1972, Schneider, Helfer, and Pollack disclosed efforts under way to design and validate a questionnaire with the goal of uncovering parents who have a potential to abuse their small children. They based their questions on their clinical experience, which suggested that parents who abuse their small children reported more severe physical punishment in their own childhood, more anxiety about dealing with their children's problems, more concern about being alone and isolated, more concern with criticism, and higher expectations for performance in their children than did nonabusers. After several

years of analysis and validation, they published first a 74-item and then a 50-item instrument, originally entitled *Survey on Bringing Up Children* (Schneider, Hoffmeister, & Helfer, 1976). The instrument has since been renamed the Michigan Screening Profile on Parenting (Helfer, Schneider, & Hoffmeister, 1977).

Although the questionnaire has not yet been sufficiently validated to be of use as a legally valid criterion in decisions regarding child placement or parental readiness to resume parenting functions, it has been shown to be capable of differentiating between attitudes regarding child rearing and regarding self-awareness and self-control functions in the parents.

With the permission of Helfer, I administered the questionnaire to several groups of parents, as discussed below, to see (a) whether abuse-potential cluster categories similar to those found by Helfer and his associates could be validated in a local sample and (b) whether scores based on the locally factor-analyzed categories could sort out abusing from nonabusing parents.

Subjects

As is typical of parents who come to the attention of public agencies (National Center on Child Abuse and Neglect, 1975), the parents referred to the participating agencies were from low socioeconomic levels. The use of such parents in the present study is not meant to suggest that abuse takes place only at low socioeconomic levels, because it does not (Spinetta & Rigler, 1972). Similarly, although more women than men have been found to abuse their children (Gelles, 1973; Gil, 1970; Smith, 1975), child abuse is not an act solely of the mother. However, the questionnaire was administered only to women to ensure nonconfounding by differences in child-rearing attitudes between men and women.

Subjects were chosen in the following manner: The participating agencies agreed to administer the questionnaire to all of the mothers currently under their jurisdiction as active cases. The questionnaire was administered to (a) adjudicated abusers, (b) spouses of adjudicated abusers, and (c) parents convicted of child neglect. The parents in these categories were chosen by the following criteria: (a) The child was under 5 years of age, and (b) court adjudication had been finalized, so that parents would not feel that their answers would affect the placement of their child or decisions regarding their own disposition. In this manner, workers were able to ensure that responses to the questionnaire were given as honestly as possible.

For purposes of comparison and contrast, the questionnaire was also administered to groups of parents who were nonabusers with children under 5 years of age. The following groups were tested: (d) nonabusing mothers from a college student population whose children were in a day-care center because one or both parents were in school, (e) nonabusing mothers from a middle socioeconomic level

whose children were in a preschool not because of necessity but through express parental wish, and (f) nonabusing mothers from a lower socioeconomic level with children in a preschool because the mother was working. Group f was chosen to match as closely as possible the educational, occupational, and socioeconomic status of Groups a, b, and c. Group d was chosen because it was similar to Groups a, b, and c in financial status but not in terms of education or potential occupation. Group e, different in terms of education, occupation, and financial status, and the most representative of the population as a whole, was chosen to test possible class differences in responding.

The samples consisted of the following numbers: (a) adjudicated abusers, 7; (b) spouses of abusers, 9; (c) parents convicted of neglect, 13; (d) nonabusing mothers from a college population, 15; (e) nonabusing mothers from a middle socioeconomic level, 15; and (f) nonabusing mothers from a lower socioeconomic level, 41.

The purpose of the study was explained in detail to the respective supervisors, the agency officials in Groups a-c, and the day-care administrators and teachers in Groups d-f. Because of the sensitive nature of the accusation of child abuse and neglect, and to prevent socially desirable responses, parents were not told specifically that the survey's ultimate purpose was to differentiate abuse potential. Rather, parents were asked if they wished to take part in a survey on attitudes in bringing up children, conducted by the university to learn how parents viewed child rearing. In accord with U.S. Department of Health, Education, and Welfare guidelines, parents were promised that the results would remain anonymous, and that any parent who wished would be given the overall results on completion of the study.

All of the parents who were approached in Groups d and e, without exception, filled out the survey as requested. Of the parents approached in Group f, all but three (93%) filled out the survey. The parents in Groups a-c were approached by assigned workers who had established rapport with them and were told that this survey would not only aid the university but that it might be of therapeutic aid to the specific worker in each case. Each worker was asked to screen out those parents who would be unduly threatened by the questionnaire, those who might be tempted to answer with socially desirable responses, and those whose cases were still pending court completion. The workers did not receive any refusals from the selected cases. The final small sample thus represents responses from parents who were motivated to fill out the questionnaires as honestly as possible. Comments from each worker on each case attested to the honest efforts of the parents who made up the final samples in Groups a-c. It is my belief that the final sample represents the cases most amenable to treatment. There is no reason to suspect that the sample represents the most severe of the abusers. On the contrary, workers' case records show that the final sample is

on the conservative side of the abuse-potential continuum in the agencies' overall abuser population. Thus, any differences that appear between the abuser and nonabuser groups would appear at least equally as strong in the general abuser population of the agencies in question. With the questionnaire aimed at being of eventual use as an aid to the therapist in sorting out areas of weakness, honest cooperation of the parents was deemed essential. In addition, honest cooperation in each of the six groups minimized confounding that would appear if the groups differed in willingness to participate.

Results

A varimax rotated factor analysis of the responses to the questionnaires was conducted by the experimenter. The six clusters of variables closely resemble the high-abuse potential categories of Helfer et al. (1977). The six resultant clusters of the present analysis are (a) relationship to one's own parents, (b) tendency to becoming upset and angry, (c) tendency toward isolation and loneliness, (d) expectations of one's own children, (e) inability to separate parental and child feelings, and (f) fear of external threat and control.

With these six factor-analyzed cluster categories as a basis, a six-column scoring form was devised, with direction of scoring set so that the higher score on each cluster represented abuse potential. Total raw scores for each subject were determined for each of the six cluster categories.

A 1×6 analysis of variance was performed for the six groups for each of the six abuse-potential categories. Table 1 gives the means and standard deviations for scores in each of the abuse-potential categories for each subject group. Table 2 gives the results of the analysis of variance for each of the six categories.

Scores on each of the six abuse-potential categories showed that significant differences existed among the six groups ($df = 5, 90$ in all cases). The resultant F on the first abuse-potential category, relationship to one's own parents, was 4.55, significant at the .001 level. The resultant F of 6.70 on the second abuse potential category, tendency to becoming upset and angry, was significant at the .001 level. The resultant F on the third category, tendency toward isolation and lone-

liness, was 7.53, significant at the .001 level. The resultant *F* on the fourth category, expectations of one's own children, was 4.20, significant at the .001 level. The resultant *F* on the fifth category, inability to separate parental and child feelings, was 3.79, significant at the .01 level. The resultant *F* of 13.92 on the sixth abuse-potential category, fear of external threat and control, was significant at the .001 level.

A posteriori tests using the Scheffé method were conducted for each of the abuse-potential clusters. Significant differences were found as follows: Group a (abusers) sig-

nificantly differed from Group e (middle-class nonabusers) in Abuse-Potential Clusters 1, 2, 3, 4, and 6. Group a significantly differed from Groups d and f in Abuse-Potential Clusters 2, 3, and 6.

Group b (spouses of abusers) significantly differed from Group e in Abuse-Potential Clusters 2, 3, 4, and 6.

Group c (neglecters) significantly differed from Group e in Abuse-Potential Clusters 1, 2, 5, and 6. Group c significantly differed from groups d and f in Abuse-Potential Clusters 2, 5, and 6.

The Scheffé a posteriori test showed that the major differences in each of the six abuse-potential categories occurred when comparison was made of one or more of the first three groups (abusers, abusers' spouses, and neglecters) with one of the latter three groups (nonabusers). The greatest differences occurred when each of the first three groups was compared to the fifth group (middle-class nonabusers). In each of the abuse-potential categories, Group e scored at the lowest level. Group d (college student nonabusers) and Group f (lower socioeconomic level nonabusers) were the next lowest in abuse potential, scoring almost identically throughout. Although the fifth group scored lowest on all of the categories, the other two nonabuser groups scored at a level not significantly higher. In contrast, the abusers scored at the highest risk level in all but one of the abuse-potential categories.

Discussion

The Michigan Screening Profile on Parenting was able to differentiate between abusing

and nonabusing mothers on personality and attitudinal variables. The empirically derived set of abuse-potential categories proved useful in significantly differentiating between abusing and nonabusing mothers within the same socioeconomic level in three areas: the tendency to becoming upset and angry, feelings of isolation and loneliness, and the fear of external threat and control. The abusing mothers differed significantly from nonabusing mothers in a middle socioeconomic level in the same categories; in their relationship to their own parents, both past and present; in having higher than normal expectations for their young children's performance; and in failing to separate their own feelings from those of their children. Although not at a significant level, abusing mothers differed from nonabusing mothers in the same socioeconomic level in the latter categories as well. Neglecting parents and spouses of abusers were also shown to be weak in the six abuse-potential categories.

Personality and attitudinal factors do make a difference. Abusing mothers differ from nonabusing mothers in areas of attitude and personality that have been clinically related to potential for abuse (Colman, 1975; Corey, Miller, & Widlack, 1975; Kent, 1976; Paulson et al., 1974; Smith, 1975; Spinetta & Rigler, 1972; Steele, 1975; Tracy & Clark, 1974; Walters, 1975). The fact that neglecting mothers and spouses of abusers also scored high on the abuse-potential categories demonstrates the power of the test in pointing to weaknesses in parental personality and attitudes that can affect the parenting role itself, regardless of whether the result is actual physical abuse, neglect of the child, or passively allowing one's spouse to abuse the child. Intervention and direction is called for in each case.

As stated above, there is no suggestion made that factors of parental inadequacy and personality weakness are the sole determinants of child abuse. Certainly, those involved in the care of the abusing parent must continue to relieve the family as much as possible of overwhelming situational stresses. However, personality does play a role. The therapist who helps the parent de-

velop the ability to maintain equanimity under stress, can be of immense aid in the rehabilitative or preventive effort.

One must caution that the questionnaire cannot be used as a legally valid criterion for sorting out abusing from nonabusing parents, since false positives have been shown on occasion (Schneider et al., 1976) and since false negatives can appear with those parents who refuse to answer the questions honestly. It is possible to fake answers by giving socially desirable responses. However, for those parents in a therapeutic situation who respond to the questionnaire with an honest desire to be helped, the responses can help point to weaknesses in areas that have been clinically shown to relate to potential for abuse. A therapist who directs interventional and preventive efforts toward the amelioration of parental attitudes, both attitudes toward the self and toward the child, is not, as Alby (1975) suggested, misdirecting energies, but is rather helping reduce deviations from the norm in characteristics related to abuse potential and, hopefully, is ultimately helping reduce the actual abusive behavior.

Effects of Intestinal Bypass Surgery on Body Concept

Peter M. Silberfarb, Patricia J. Phelps,
Peter Hauri, and Charles Solow
Dartmouth Medical School

Stability of body concept, as reflected in the Draw-a-Person Test, was demonstrated in 14 patients undergoing bypass surgery for severe obesity. Three Articulation-of-Body Concept scores for each patient were obtained: at the preoperative level, within 1 year subsequent to surgery, and at least 2 years after the operation. During the first year after the operation, body concept was significantly poorer than at the preoperative level. However, patients recovered from their postoperative disruption of body concept within 2 years after the operation and then reached at least a preoperative level. Thus, the shock of the bypass operation seemed to cause a temporary disruption in this otherwise extremely stable personality dimension.

Field dependency has become an important personality dimension when attempting to explain individual patterns and styles of behavior (Witkin, Dyk, Fatereson, Goodenough, & Karp, 1962; Witkin, Goodenough, & Karp, 1967). Field-dependent individuals, when presented with an organized Gestalt, appear to have difficulty separating out parts of that whole, whereas field-independent persons are more able to perceive the discrete parts of a complex pattern as separate from each other (Witkin et al., 1962). The degree of field dependency within a certain individual appears to manifest itself in drawings of the human figure. Specifically, field-dependent persons show less articulation of body parts in their drawings than do field-independent individuals.

An Articulation-of-Body Concept (ABC) scale for children has been developed and validated by Marlen's (Fatereson & Witkin, 1970;

Witkin et al., 1962). This scale basically reflects three characteristics: (a) the extent of identity and sex differentiation in the figure drawings, (b) the amount of detail in the drawings, and (c) the form level of the figures (i.e., general body shape and integration on features). Low scores indicate relatively primitive drawings, and higher scores are given for more sophistication. As predicted, children who score higher on the Marlen's scale generally are found to be more field independent on other measures as well, whereas children who draw relatively unarticulated figures are more field dependent (Witkin et al., 1962). Studies containing adults indicate similar relationships (Reitman & Cleveland, 1964; Witkin et al., 1962). Occasionally, the 5-point Marlen's ABC scale is extended to a 9-point scale in adult studies, and this 9-point version was used in the current evaluation.

An individual's level of field dependency appears to be stable. It is not changed by such interventions as sensory isolation (Reitman & Cleveland, 1964), electroconvulsive shock (Pollack, Kahn, Karp, & Fink, Note 1), and drugs, including chlorpromazine, imipramine, and alcohol (Karp, Witkin, & Goodenough, 1965; Pollack et al., Note 1). However, the question still remains as to how much the stability of a person's score on

This study was supported in part by Grant 1R03MH17294-1 from the National Institute of Mental Health.

We wish to thank Marlen's and Witkin for help in preparation of this manuscript and Swift for initial work in collection of the clinical data.

the Marlens scale is dependent on the stability of physical body over time. Although some of the manipulations studied so far have threatened body appearance, none have actually changed an individual's body appearance in any dramatic way.

An ideal opportunity to study the stability of body articulation scores presented itself when drawings were collected from patients undergoing jejunoileostomy, an operation that drastically alters body appearance. Jejunoileostomy (intestinal bypass surgery for massive obesity) leads to a relatively consistent, substantial, and lasting weight reduction. Weight stabilizes after 1 or 2 years, usually at somewhat above ideal levels. The procedure, however, has distressing side effects and complications that are sufficiently common to require caution and restraint in the use of this therapeutic approach.

The specific question investigated in this study is whether the drastic and lasting changes in a person's body appearance secondary to jejunoileostomy lead to temporary or chronic changes in body concept as measured by the Marlens scale. This question seemed relevant, because field dependency (indirectly measured by the Marlens scale) has assumed a fair amount of importance in psychological testing and personality theory.

Method

Subjects

Twenty-nine patients were tested and interviewed before and after jejunoileostomy and at follow-up, at least 2 years later, as part of an investigation concerning the psychological sequelae of jejunoileostomy (Solow, Silberfarb, & Swift, 1974). Of these 29 patients, three scorable figure drawings (at preoperative, postoperative, and follow-up levels) were collected only from 14 patients. In 10 cases, the interviewer did not ask for figure drawings on all three occasions, because they had not been part of the test battery as originally planned. Five other patients drew stick figures on at least one of the three occasions. Such stick figures cannot be rated on the Marlens ABC scale.

Of the 14 patients who produced sets of three ratable figures, 10 were women and 4 were men. The ages ranged from 21 to 50 ($M = 36$ years). Preoperative weights ranged from 102 kg to 223 kg ($M = 151$ kg), representing from 39 to 160 kg over desirable weight (M overweight = 84 kg). Mean weight loss at follow-up was 60 kg, with a range of 32 kg to 117 kg. Only 2 of the patients had be-

come obese in adulthood; the others had been overweight since before the age of 16. All patients had been severely obese for years and had tried many diets without long-lasting success.

Eight of the patients in this study had been referred for jejunoileostomy by their physicians, and 6 were self-referred, although motivation was mixed in most cases. Five sought surgery primarily because of somatic concerns, whereas 9 were motivated primarily by psychosocial concerns such as the need to improve appearance, marriage, and so forth.

Nine patients were considered reasonably well adjusted before the bypass operation, and five were seen as distinctly impaired psychologically. Among the latter, four were diagnosed neurotic, and one was believed to have a personality disorder. Deficient self-esteem, marked self-consciousness about appearance, and vocational impairment characterized at least two thirds of the total group and appear to be related to the restriction of physical and social activity caused by their massive obesity.

Procedure

Each patient was interviewed three times by a trained psychiatrist, once at the preoperative level [within 1 week ($M = 4$ days) before surgery], once at the postoperative level [from 161 to 370 days ($M = 235$ days) after surgery], and once at follow-up (at least 2 years after the bypass operation). During each of these interviews, the patient was asked to draw a person. Interviewers did not know the purpose of this request and were unfamiliar with the theory behind the Marlens ABC scale.

For scoring, each drawing was randomly assigned a code number. All other identifying marks were removed from each drawing except for identifying the patient as either male or female. Marlens, the developer of the 9-point ABC scale, then rated the drawings in a random order. Marlens knew nothing about the purpose of this experiment except that all drawings came from adults.

Statistical Analysis

Ratings were evaluated by a two-way analysis of variance using a mixed repeated measures design. [The 14 patients were interpreted as a random variable, and the three conditions (preoperative, postoperative, and follow-up levels), as a fixed variable.] When the analysis of variance showed significance, differences among the three conditions were further evaluated by matched t tests. Finally, Pearson correlation coefficients were computed among the three conditions (preoperative, postoperative, and follow-up levels) and were adjusted for multiple comparisons by Sheffé's method.

Results

Table 1 indicates the mean ABC ratings: They were similar at preoperative and fol-

Table 1
Mean Articulation of Body Concept Ratings

Time of drawing	M ABC rating	SD
Preoperative ($M = 4$ days)	6.29	2.70
Postoperative ($M = 235$ days)	5.43	2.34
Follow-up ($M = 32$ months)	6.43	2.50

Note. ABC = Articulation-of-Body-Concept scale.

low-up levels but were somewhat lower (less well articulated) at the postoperative period. (For overall results of other interview data, see Solow et al., 1974).

Tables 2 and 3 (correlational analysis) document the consistency of ABC ratings over time. Most of the variance in Table 2 was due to variability from one patient to the other ($F = 18.40$, $p < .001$). Similarly, correlations from preoperative to postoperative and follow-up levels were highly significant, suggesting high test-retest reliability of the ABC scale over a fairly extended time period.

Within this overall stability of the ratings, there was a slight but nevertheless significant decrease of ABC scores postoperatively. This is indicated by the significant "time of drawing" effect in Table 2 ($F = 3.19$, $p < .05$) and by the t -test analyses in Table 3: Scores significantly decreased from preoperative to postoperative levels but increased again at follow-up.

Although the postoperative drawings were scored significantly lower than either the preoperative or the follow-up drawings, weight loss (either in percentages of kilo-

** $p < .001$.

grams) was not significantly correlated with the deterioration in ABC scores from preoperative to postoperative tests.

Discussion

The most important result of this study is the remarkable consistency in the patients' scores on the ABC scale from the preoperative level to follow-up, even though these patients underwent marked changes in their own body appearance. (Mean weight loss was 60 kg!) This consistency in ABC scores in the face of marked body alteration supports the hypothesis that the degree of articulation of body concept in adults is *not* directly related to the patient's physical appearance. In addition, this finding is made more interesting by the fact that the massive weight reduction undergone by these patients must have also affected their postural experience.

One rationale for using human figure drawings in psychological testing is that they reflect the patient's degree of field dependence. The present study suggests that in

Table 3
Comparisons Among the Three Sets of ABC Ratings

Sets compared	Time between compared sets	t	r
Preoperative vs. postoperative	$M = 239$ days	3.39***	.84****
Preoperative vs. follow-up	at least 2 years	.33	.81****
Postoperative vs. follow-up	at least 1 year	2.37*	.72**

* $p < .04$.

** $p < .01$.

*** $p < .005$.

**** $p < .001$.

adults, this concept is relatively fixed, because marked alteration in the physical shape and size of the body did not change the ABC scores at follow-up. If body concept were a more fluid entity, one might expect figure drawings to change in proportion to the amount of body change incurred after the bypass surgery. There was no correlation, however, between the change in ABC scores and total weight lost.

A second finding in this study lies in the fact that the jejunoileostomy did, temporarily, shift the patients toward less sophisticated figure drawings, possibly indicating a temporary shift toward more field dependence after the operation. It seems unlikely that reduced motivation to draw the figure could have played some role in causing less articulated drawings after surgery. High test-retest reliability commonly found for ABC scores suggest that body articulation is only minimally influenced by transient factors such as motivation (Faterson & Witkin, 1970). Also, it would be difficult to explain how reduced motivation could occur so consistently across subjects. Rather, it seems that the postoperative period of intestinal bypass surgery is a time of major readjustment, and one might speculate that this drastic alteration of one's body may have disrupted the body image temporarily.

In summary, jejunoileostomy in massively obese patients seemed to cause a temporary decrease but no permanent change in the articulation of body concept. Thus, field dependence seems to remain stable not only in relation to the effects of sensory isolation, drugs, and electroconvulsive therapy (as pre-

viously demonstrated) but to dramatic changes in actual body configuration as well. This stability is in sharp contrast to the changes noted in other psychological variables following jejunoileostomy surgery such as self-esteem and self-consciousness (Solow et al., 1974). This lends further support to the concept of field dependence as an enduring personality trait.

Effects of Sex, Social Desirability, and Birth Order on the Defense Mechanisms Inventory

Gary E. Dudley
Georgia Southern College

This study investigated the effect of sex difference, social desirability instructions, and the birth order of respondents on the Defense Mechanisms Inventory (DMI). Using 30 male and 30 female undergraduates, half of the subjects in each group were given regular instructions, and the other half were instructed to respond so as to present a favorable impression. It was hypothesized that a sex difference would be found on Turning-Against-Others (TAO) and Turning-Against-Self (TAS) and that social desirability instructions would result in significant differences for TAO, Projection (PRO), Principalization (PRN), and Reversal (REV). It was further hypothesized that firstborns would report less TAO than later borns. In contrast to previously published reports on the DMI, a sex difference was found on PRO only. Further, social desirability effects were found on TAO, PRO, PRN, and REV. Thus, an interpretive caution is in order regarding the use of the DMI, but its potential clinical utility suggests that further research is warranted.

Although interest in and use of the notion of "defense mechanisms" is firmly ingrained in clinical practice, research on the cognitive and behavioral operations involved is remarkably absent in academic psychology. In a recent publication, Gleser and Ihlevich (1969) reported on the Defense Mechanisms Inventory (DMI). The DMI represents the first attempt to derive a comprehensive, objective, and behaviorally stated test of the traditionally defined mechanisms of defense. The test provides subjects with a checklist of possible situations, and the subjects are asked to indicate what would be their most likely and their least likely reactions. Scores on five defense clusters are derived from the responders' rankings: Turning-Against-Others (TAO), Projection (PRO), Principalization (PRN), Turning-Against-Self (TAS), and Reversal (REV). (See Gleser & Ihlevich, 1969, for a detailed description of each defense cluster.)

The DMI has found a useful role in the medical setting inasmuch as practitioners are generally interested in making a statement about the structure and function of psychological defenses in evaluating surgical and other medical patients. Two recently reported studies lend some support to the construct validity aspect of the DMI in this area. Gur and Gur (1975) reported that persons who scored high on REV (repressive/denial defenses) had significantly more psychosomatic complaints than persons who used affect-expressive defenses of TAO or PRO. Klein, Gonen, and Smith (1975) reported that high TAS and REV scores were consistent with the psychogenic diagnosis of a patient with painful ecchymosis following surgery for a herniated lumbar disc. Similarly, Scholz (1973) reported on 35 suicide attempters paired with 35 nonsuicidal neuropsychiatric patients. As hypothesized, suicide attempters displayed significant differences on the TAS dimension.

Psychometric data on the DMI suggest adequate reliability, although one study found a sex difference on three of the five defense scales, with males scoring higher on

This research was supported by Grant 0377 from Georgia Southern College.

TAO and PRO and females scoring higher on TAS (Weissman, Ritter, & Gordon, 1971). Gleser and Ihlevich (1969) originally reported a sex difference for TAS only. Finally, in another construct validity study, Gleser and Sacks (1973) reported that the DMI adequately predicted actual behavior in a conflict situation for males but not for females. One possible explanation for this finding is the influence of a social desirability factor on the females' reactions to the experimental manipulation. In fact, the social desirability aspects of the DMI have not been evaluated. Such an evaluation may help clarify the potential clinical utility of the DMI. Further, since published results are inconsistent with regard to sex differences, and since it is possible, for example, that the effects of sex and social desirability may have been influential in the Gleser and Sacks study, the DMI was evaluated to determine the maximum extent to which it may be influenced by social desirability in the context of sex differences. It was hypothesized that sex differences would be found for TAO (males higher) and TAS (females higher) and that main effects would obtain for social desirability instructions on TAO, PRO, PRN, and REV. Finally, firstborns were expected to use TAO less than later borns. This hypothesis was based on the findings of Warren (1966) that firstborns tend to be more concerned with social desirability than later borns and the view that TAO would be seen as a less socially desirable mode of conflict resolution. It also served as a more subtle indicator of the social desirability features of the DMI.

Method

Subjects

The study contained 60 undergraduate students from an introductory psychology class. There were an equal number of males and females ranging in age from 18 to 23 years ($M = 19.1$).

Procedure

All students completed the DMI and provided information about birth order and age. One group was given regular instructions as provided with the

DMI. The second group was given social desirability instructions. Each group consisted of 15 males and 15 females. The social desirability instructions consisted of a modification of Paragraphs 2 and 4 in the regular instructions. These paragraphs were modified to read as follows:

What we want you to do is to select the *one* answer of the five which you think is most *socially appropriate*. That is, select the answer which is most likely to create a favorable impression in the social situation, and fill in the box labeled "T" by the number corresponding to that answer on the attached answer sheet. Then select the *one* answer which you think is least favorable or least socially appropriate and fill in the box by that number labeled "F." Remember: You are *not* to answer in the way that you would necessarily react but in the way a person would react who is trying to create a favorable social image.

There are no right or wrong answers here; the only thing that should guide your selections is your knowledge about how to create a favorable image of yourself. Allow your mind to imagine for a moment that the event described in the story is really happening to you, even though you may never have experienced such an event. Remember, we are *not* asking what *your* behavior and responses would be but rather your opinion of what the likely behavior would be of someone trying to present themselves favorably in our society.

The data were analyzed by multivariate analysis of variance with sex and instructions as independent variables. A *t* statistic was derived to test the hypothesis of a birth-order difference on TAO.

Results

Multivariate analysis of variance on the five dependent measures resulted in a significant overall main effect for instructions, approximate $F(5, 52) = 12.20$, $p < .01$ (Dixon, 1973). The interaction was not significant. Subsequently, each dependent measure was evaluated in a univariate analysis of variance that produced significant main effects for sex on PRO, $F(1, 56) = 5.79$, $p < .05$, and for instructions on TAO, PRO, PRN, and REV, $F(1, 56) = 32.28$, $p < .001$, $F(1, 56) = 16.63$, $p < .001$, $F(1, 56) = 12.59$, $p < .001$, and $F(1, 56) = 52.28$, $p < .001$, respectively. Even though no interactions were significant, there was a tendency for males to decrease TAS under social desirability instructions, $t(58) = 1.4$, $p < .20$,

whereas females showed no change in TAS in the social desirability condition. Finally, firstborns scored significantly lower on TAO than later borns ($M_s = 32.1$ and 39.0 , $SD_s = 7.96$ and 7.01 , respectively) as predicted, $t(58) = 2.33$, $p < .05$, see Table 1).

Discussion

Based on the results of this study, it is clear that the question of sex differences in defensive style is unresolved. In contrast to two earlier studies (Gleser & Ihlevich, 1969; Weissman et al., 1971), the present study failed to demonstrate a sex difference for TAS. Further, the finding that males scored higher than females on PRO is consistent with Weissman et al., but their additional sex difference on TAO did not occur in this study. Some of these discrepancies may be a function of regional differences in the sample. Previous studies were done in Northern cities, whereas subjects in this study were primarily from the rural South. Specifically, the influence of the Southern Baptist religious orientation (40% of the sample) may have militated against the selection of TAO defenses in both sexes. The fact that PRO, related to TAO in terms of the direction of affective expression, was used more by males than females suggests that although males did not report a direct response against the frustrating object or person, they were willing to attribute negative characteristics to frustrating persons. This represents a more subtle form of aggression and externalization of negative affective experience. It should be noted that the present male sample had a mean TAO score of 33.6 compared to the mean TAO score of 40.9 reported for a college sample by Gleser and Ihlevich (1969). The absence of a sex difference for TAS in the present sample is inconsistent with all previously published reports. Higher intro-punitiveness in males may also be a function of the sample, however, and the effects of socioeconomic level, religious orientation, and demographic variables should be explored. Alternatively, one of the most serious shortcomings of the DMI in its present form is that it is an ipsative measure. Thus, given the data from this study, it is likely that one

Table 1
Means and Standard Deviations for DMI Subscales With Regular and Social Desirability Instructions

Instructions	Males		Females	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
DMI				
TAO	33.6	12.4	36.6	8.1
PRO	39.5	5.1	37.3	5.0
PRN	46.5	5.6	44.8	5.6
TAS	40.1	9.9	40.5	6.8

TAO	21.5	12.4	17.9	8.3
PRO	35.1	6.0	30.9	4.2
PRN	50.5	6.7	51.5	5.5
TAS	36.3	8.5	39.7	5.8
REV	56.6	10.5	60.0	10.3

Note. DMI = Defense Mechanisms Inventory; TAO = Turning-Against-Others; PRO = Projection; PRN = Principalization; TAS = Turning-Against-Self; REV = Reversal.

or the other of the discrepant findings (low TAO in males or high TAS in males) is related to the ipsative property of the instrument. (For a comprehensive treatment of this psychometric issue, the reader is referred to Block, 1957; Broverman, 1962; Cattell, 1944.)

The findings related to social desirability have important implications for the clinical utility of this instrument. The present sample readily identified the TAO and PRO items as less desirable than the PRN and REV items. Thus, if there is any motivation to present a favorable picture of oneself, it seems clear that the instrument in its present form does not provide adequate safeguards. A more subtle indicator of the social desirability effect is provided by the finding that firstborns, generally considered to be more inclined to respond in socially desirable ways (Warren, 1966), in fact scored lower on TAO (a defensive style that was avoided by persons given social desirability instructions) than did later borns.

In summary, the DMI is a promising instrument in research on defensive and coping processes in personality research. It seems almost certain that it will find increasing util-

ity in psychosomatic medicine (Gur & Gur, 1975; Klein et al., 1975). The present study provides data that suggest the need for caution, however, in using the instrument clinically because of apparent high susceptibility to the influence of social desirability response biases. Finally, the ipsative nature of the instrument in its present form has been noted, and the psychometric problems posed in this regard should be explored in subsequent research.

Blood Nicotine and Carboxyhemoglobin Levels After Rapid-Smoking Aversion Therapy

M. A. H. Russell, Martin Raw, C. Taylor,
C. Feyerabend, and Y. Saloojee
University of London, London, England

Blood nicotine and carboxyhemoglobin (COHb) levels after rapid smoking were studied in 15 smokers. Blood nicotine averaged 48.1 ng/ml after rapid smoking compared to 32.4 ng/ml after normal smoking ($p < .002$), and COHb levels averaged 12.1% and 8.9%, respectively ($p < .001$). Normal smoking levels of 92 smokers in other studies averaged around 30 ng/ml nicotine and 8.2 to 8.5% COHb. There was no evidence that the degree of nicotine and carbon monoxide intoxication produced during rapid smoking had any relation to the reduction in the desire to smoke immediately after the session or to the decrease in cigarette consumption on the following day. The potential risks of rapid smoking are discussed. It is suggested that these risks might be reduced by using a beta adrenergic blocker and that the procedure could be made completely safe, possibly without loss of treatment effect, if subjects were instructed not to inhale.

Among the many aversive techniques devised for the treatment of dependent cigarette smokers, none have so far shown a consistent specific effect when subjected to controlled trial or replication by other research workers. A possible exception is a method of rapid smoking developed by Lichtenstein and his colleagues (Lichtenstein & Danahar, 1976; Lichtenstein, Harris, Birchler, Wahl, & Schmahl, 1973). The procedure involves subjects smoking their usual brand of cigarettes in a rapid and continuous manner, inhaling one puff every 6 sec until no further smoking can be tolerated. It is not clear how much the aversiveness and the subjects' tolerance limits are determined by nicotine intoxication or by local irritation of the mouth and respiratory tract.

Hauser (1974) has pointed out that excessive intake of nicotine could induce cardiac arrhythmia, especially in subjects with

coronary heart disease. Screening to completely exclude coronary heart disease is virtually impossible, and a normal resting (or even posteffort) electrocardiograph is no guarantee of freedom from such disease. Despite Hauser's plea for caution, "thousands of smokers have undergone rapid smoking, many of them in a commercial program operated by Schick Laboratories" (Danahar, Lichtenstein, & Sullivan, 1976, p. 556).

In a therapeutic situation, a degree of risk is justified, provided that it is necessary to offset an even greater risk. Assessment of these risks requires consideration of both severity and probability of the potential consequences of having treatment and going without it. Clearly, therapy should go ahead only if the balance is in the subjects' favor. Furthermore, the assessment should be made in consultation with the subjects, for it is their own evaluation of the severity of consequences that should count. The therapist's role in a decision that is not of clear and obvious overall benefit to the subject should be confined to providing information on the nature and probability of possible hazards.

At present, information on rapid smoking

is deficient not only with respect to the degree of hazard, but some doubt also exists as to whether there is any specific benefit. Apart from the numerous other factors in the treatment situation (attention placebo, self-monitoring, persuasion from the therapist etc.), the specific contribution of rapid smoking has been small and in some cases only transient (Lando, 1975). Indeed, Lichtenstein himself in his latest appraisal modestly concluded that "it must be acknowledged that the magnitude of the rapid smoking effect does not appear to be large . . . the interpersonal/persuasive aspects of the treatment setting are a significant source of variance" (Lichtenstein & Danaher, 1976, p. 99).

Of the many toxins present in tobacco smoke, excessive absorption of nicotine and carbon monoxide (CO) represent the greatest potential hazards of rapid smoking, for it is the acute toxic effects that are relevant to this situation rather than the long-term hazards such as lung cancer. Aronow (1976) has reviewed the literature on the effects of nicotine and CO on coronary heart disease. At levels produced by normal smoking, the effects of CO and nicotine interact in such a way as to increase the risk of a sudden heart attack and also to increase the risk of sudden death in the event of such an attack. The interaction is complex but consists basically of the setting up of interrelated vicious cycles. For example, nicotine increases the oxygen requirement of heart muscle, whereas carboxyhemoglobin (COHb) reduces its availability. COHb also impairs the pumping power and efficiency of the heart muscle, leading to further deterioration in its oxygen supply. When the heart muscle is suffering from lack of oxygen, both nicotine and COHb reduce the ventricular fibrillation threshold or, in other words, increase the risk of developing a fatal loss of rhythm.

Few studies have attempted to estimate the hazards of rapid smoking. One study showed that blood COHb, an index of CO absorption, increased from an average of 4.2% before to 7.3% after rapid smoking (Dawley, Ellithorpe, & Tretola, 1976). Un-

fortunately, no details are given as to the method of rapid smoking used, and crucial data such as rate, duration, and number of cigarettes smoked during the session are not mentioned. Another study by Lichtenstein and his colleagues (Danaher et al., 1976) showed that rapid smoking produced a significantly greater rise in heart rate than normal smoking, but they also found that CO absorption was not significantly greater. However, their method of COHb estimation was somewhat archaic, and they conceded the need for further study using more sophisticated measures. More recently, Horan, Hackett, Nicholas, Linberg, Stone, & Lukaski (1977) have reported the occurrence of electrocardiographic abnormalities during rapid smoking, and they suggested that these may be due to nicotine intoxication (Horan, Linberg, & Hackett, 1977). Indeed, they commented that "normative data on the amount of nicotine absorbed by subjects during rapid smoking are an urgent research priority" (Horan, Linberg, and Hackett, 1977, p. 346).

We are conducting an evaluative trial of rapid smoking among subjects attending a tobacco withdrawal clinic. Full analysis of our findings is awaiting long-term follow-up. However, in those subjects randomly assigned to rapid smoking, we have measured blood nicotine and COHb levels after normal smoking and after their first session of rapid smoking. We have also been able to compare the levels produced in these subjects by rapid smoking with the average normal-smoking levels of subjects from a number of previous studies. Finally, to see whether nicotine intoxication contributes to the therapeutic effect, we have examined the relation between the degree of excessive nicotine intake during rapid smoking and the reduction in cigarette consumption on the day after the first session.

These findings are presented here, and the implications for the possible hazards of rapid smoking are discussed. No other study has measured nicotine intake from rapid smoking, and excessive nicotine intake is the main potential hazard. It was indeed the main concern of Hauser (1974).

Method

Subjects

The subjects were 5 men and 10 women who attended the Smokers Withdrawal Clinic at the Maudsley Hospital, London, England, and who volunteered to take part in a clinical trial of some "new behavioral treatments." The trial in question was a straight comparative study of rapid smoking, cue exposure, and simple support. (This study is still in progress at the stage of long-term follow-up.) Subjects were excluded if they had a clinical or family history suggesting the possibility of coronary heart disease. All men over 40 years old and women over 50 were excluded even in the absence of such evidence. Of the 17 eligible subjects who were randomly assigned to rapid smoking, complete blood data were missing for 2; 1 had a needle phobia, and in the case of the other, a specimen tube was broken in the laboratory.

Procedure

Venous blood samples were taken on the day of the first session of a course of rapid-smoking treatment. The sessions took place in the late afternoon (between 4 p.m. and 6 p.m.), and subjects were instructed to smoke normally until the start of treatment. On arrival at the clinic, they were asked to smoke a cigarette in their usual way, and a blood sample (normal-smoking sample) was then taken 2 minutes after the cigarette was completed. The blood nicotine concentration falls rapidly from a peak just after a cigarette. In all of our studies, we have used a time interval of 2 minutes after a cigarette to approximate to the peak level of nicotine. The rapid-smoking session was started about 15–20 minutes after the normal-smoking sample, and a second blood sample was taken as close as possible to 2 minutes after completion of the last trial of the session. As the sessions were given in small groups of four or five subjects, it was not always possible to take the blood within 2 minutes of discarding the last cigarette of the session. For one or two subjects, it was taken at 4–6 minutes. The error from such delay would tend to make the rapid-smoking nicotine values appear slightly lower than their true levels.

To have reversed the order of sampling in half of the subjects by taking the normal-smoking sample after the rapid-smoking sample might have been methodologically more correct, but a cigarette taken even 30 minutes after a rapid-smoking session would not have been quite "normal." Besides, the subjects had been smoking normally all day, and the cigarette smoked for the "normal-smoking sample" would have had little extra effect on the nicotine level of the "rapid-smoking sample" (Russell, Feyerabend, & Cole, 1976).

The rapid smoking was conducted as follows: The subjects were instructed to puff and inhale deeply every 6 sec and to continue for as long as

possible, even if it meant lighting a second or third cigarette. This was followed by a 5-min rest, after which the sequence was repeated for up to three trials if necessary. Many subjects felt unable to face a third trial.

The desire to smoke was rated on a 7-point scale before the first and after the last trial. The ratings were as follows: 0 = none, 1 = very slight, 2 = slight, 3 = moderate, 4 = fairly strong, 5 = strong, 6 = very strong.

Blood Analysis

Blood samples were analysed for COHb using an IL 182 CO-oximeter (Russell, Cole, & Brown, 1973) and for nicotine using gas chromatography (Feyerabend, Levitt, & Russell, 1975). The laboratory workers who did the analysis were unaware of the design or purpose of the study.

Results

Individual data are shown in addition to the means (Table 1). When individual risk is involved, it is relevant if only 1 case in 20 shows an excessive or unusual response.

Rapid Smoking in Practice

The amount of rapid smoking undertaken was subjectively determined by the individual's own tolerance. Seven subjects had three trials and seven had two trials, but Subject 15 (Table 1) could manage only one trial. On average, 3.3 cigarettes were smoked during the session at a rate of 2.5 min per cigarette. Thus, at 1 puff every 6 sec, a mean of 25 puffs was obtained from each cigarette, which is at least double the number taken during normal smoking and by the standardized puffing of the smoking machine at routine analysis of tar and nicotine yields (Rothwell & Grant, 1974). The total duration of smoking during the session averaged 8.3 min, but it varied widely between subjects, ranging from 2 min (Subject 8) to 14.25 min (Subject 4). There was a tendency for the amount of rapid smoking tolerated to decrease with each successive trial. The average duration of the trials were 4.6, 3.0, and 2.1 min for Trials 1–3, respectively, and the average number of cigarettes smoked per trial were 1.7, 1.4, and .8, respectively. The tolerance limits were determined by irritation to the mouth and throat (six subjects) or by

<i>M</i> \pm <i>SD</i>	± 13.7 (12.1)	$\pm .3$	± 1.1	± 2.8	± 3.4	± 11.6	± 15.7

Note. The data for daily cigarette consumption are the self-recorded levels, with the initial levels claimed in parentheses. Subject 1 rolled his own cigarettes, so that the nicotine yield was unknown. None of the differences between men and women were statistically significant.

* These subjects tolerated three trials during the session; the others all had two trials except Subject 15, who managed only one trial.

nausea (nine subjects), but no subject vomited. The experience of nausea was not significantly associated with either relative or absolute increase in plasma nicotine level after rapid smoking.

Carbon Monoxide Intake

COHb levels before and after rapid smoking are shown in Table 1. In view of the slow removal of CO from the body, especially under sedentary conditions, the decrease over the 15- to 20-minute period between taking the "before" sample and starting rapid smoking would have been small (< .5% COHb; Russell, Wilson, Cole, Idle, & Feyerabend, 1973). However, this means that the full increase attributable to rapid smoking

would have been a little more than the average increase per subject of 3.2 ($SD = .9$) % COHb. As expected, the difference between the mean COHb before and after rapid smoking was highly significant, $t(14) = 12.99$, $p < .0001$. The increase in COHb was related to the number of cigarettes smoked in the session, $r(14) = .81$, $p < .01$, and to the total duration of smoking during the session, $r(14) = .58$, $p < .05$, but it was not significantly greater in those who tolerated three compared to two trials during the session (3.5 vs. 2.9% COHb), $t(11) = 1.2$, *ns*.

Plasma Nicotine Levels

The comparison of plasma nicotine concentrations after rapid smoking with peak

levels obtained from normal smoking are shown in Table 1. The average of 48.1 ng/ml after rapid smoking is significantly higher than the normal smoking mean of 32.4 ng/ml, $t(14) = 4.01$, $p < .002$. Plasma nicotine decreases rapidly over the first 10–15 minutes after completing a cigarette (Isaac & Rand, 1972), so that the levels after rapid smoking would have been even higher had all the blood samples been taken within 2 minutes of completing the last trial. It is probable that a slight delay in taking the blood accounted for the few subjects whose rapid-smoking levels did not substantially exceed the normal-smoking level (e.g., Subjects 8, 10, and 13). However, no record was kept as to which subjects did experience such delay. The average relative excess of plasma nicotine after rapid smoking was 48% above the normal-smoking level (Table 1).

The plasma nicotine after rapid smoking was related to the number of cigarettes smoked in the session, $r(14) = .55$, $p < .05$, and to a lesser extent with total duration of smoking during the session ($r = .44$, *ns*). There was no significant difference in the levels obtained by those who tolerated three versus two trials, for whom the means were 48.3 and 47.5 ng/ml, respectively. Plasma nicotine levels after normal smoking and rapid smoking were not significantly correlated ($r = .42$, *ns*). The association between the subjects' plasma nicotine levels and their usual cigarette consumption was statistically significant for rapid smoking, $r(14) = .56$, $p < .05$, but not for normal smoking ($r = .37$, *ns*). The nicotine yield of the cigarette smoked seemed to have little effect on the plasma nicotine level produced ($r = .40$, *ns*, for normal smoking; and $r = .06$ for rapid smoking).

Heart Rate

Pulse rate was counted for only four subjects. However, it seemed clear that the increase was produced by the first rapid-smoking trial and that the second trial produced no further increase. The four subjects had a mean rate of 88 per minute before start-

Table 2

Lack of Relation of Treatment Effects of the First Session to Rapid-Smoking Variables and Plasma Nicotine and Carboxyhemoglobin (COHb) Increase During Rapid Smoking

Variable	Reduction in desire to smoke	% reduction in cigarette consumption on day after the session
<i>M</i> for subjects who had		
2 trials ^a	3.7	75.4
3 trials ^a	2.7	55.8
<i>t</i>	1.04	.99
Product-moment correlations ^b		
No. cigarettes smoked in session	.33	.27
Time taken to smoke each cigarette	-.21	-.38
Total smoking time in session	.13	-.04
Increase in COHb%	.29	.22
Blood nicotine after rapid smoking	.30	.28
Ratio of rapid- to normal-smoking blood nicotine	.21	.29

Note. One subject (15) tolerated only one trial. For a sample size of 15, a 5% level of significance requires a correlation of .51 or more. The reduction in the rating of desire to smoke over the course of the session correlated .60 with the percentage of reduction in cigarette consumption on the following day.

^a $n = 7$.

^b $n = 15$.

ing the session. This increased to 106.5 after the first and 104.7 after the second trial.

Treatment Response to Rapid Smoking

A full assessment of the value of rapid smoking as a treatment for smokers will be reported separately after a 1-year follow-up, but two potentially relevant variables for treatment outcome deserve mention here because of their lack of significant association with the amount of rapid smoking in the session or the degree of nicotine and CO intake (Table 2).

Subjective ratings of desire to smoke. The average rating of 3.7 ($SD = 1.7$) before the session decreased to .6 ($SD = 1.0$) just after the last trial, $t(14) = 6.87$, $p < .001$.

Table 3

Means \pm Standard Deviations for Blood Nicotine and Carboxyhemoglobin Levels After Rapid Smoking Compared to Normal Smoking Data From Other Studies

Study	No. subjects	Usual daily cigarette consumption	COHb (%)	Plasma nicotine (ng/ml)
Other				
Russell, Wilson, Patel, Cole, and Feyerabend (1973); Russell, Wilson, Patel, Feyerabend, and Cole (1975)	10	27.2 \pm 6.9	8.2 \pm 2.2	30.1 \pm 10.7
Russell, Wilson, Feyerabend, and Cole (1976)	43	33.3 \pm 17.1	8.5 \pm 2.6	30.1 \pm 12.5
Russell, Sutton, Feyerabend, Cole, and Saloojee (1977)	21	33.1 \pm 11.5	8.2 \pm 2.7	31.5 \pm 12.4
Sutton, Feyerabend, Cole, and Russell (1978)	18	28.8 \pm 9.8	8.5 \pm 2.1	29.0 \pm 17.3
Present				
Normal smoking	15	29.1 \pm 13.7	8.9 \pm 2.8	32.4 \pm 11.6
Rapid smoking			12.1 \pm 3.4	48.1 (\pm 15.7)

Note. COHb = carboxyhemoglobin. Blood samples were all taken in the afternoon approximately 2 minutes after completing a cigarette. With the exception of rapid smoking, all subjects had spent the day smoking their usual brand of cigarettes in their usual manner.

The subjects had been smoking normally and had not been deprived before the session, so the initial rating was not very high.

Self-recorded cigarette consumption. On the day after the rapid-smoking session, cigarette consumption decreased on average to 32.7% ($SD = 34.4$) of the baseline level before treatment. Only 4 of the 15 subjects failed to achieve a reduction of at least 50%, and 3 did not smoke at all.

Discussion

There seems little doubt from our data that rapid smoking can give rise to blood levels of nicotine and COHb that greatly exceed those produced by the normal smoking of very heavy smokers. Our data from five different studies, comprised of 107 smokers, are consistent (Table 3). They show that our subjects have been heavy smokers with an average consumption of about 30 cigarettes per day compared to a national average in Britain of 22 per day for men and 16 per day for women (Lee, 1976). With normal smoking, COHb levels taken during the afternoon approximately 2 minutes after a cigarette averaged 8.0%–8.5%, whereas plasma nicotine averaged about 30.0 ng/ml. In contrast, rapid smoking produced an average

COHb of 12.1% and a plasma nicotine concentration of 48.1 ng/ml. The average increase in % COHb during a rapid-smoking session was 3.2, which is the same as the increase found by Dawley et al. (1976).

Since nicotine and CO intake from normal smoking constitute a risk for people with coronary heart disease (Aronow, 1976), the risk must be greater during rapid smoking. Unfortunately, the magnitude of the risk is not easily assessed. In the first place, no one has yet attempted to quantify the short-term risk of say 1 day of normal smoking to subjects with severe coronary heart disease, let alone for subjects without evidence of such disease. Had our data shown that plasma nicotine and COHb levels after rapid smoking were no higher than after normal smoking, we could have concluded that the risks did not increase. This was clearly not the case, so that one is beholden to make some attempt to assess the risks.

On the average, plasma nicotine levels after rapid smoking were about 50% higher and COHb levels 36% higher than after normal smoking. It is unlikely that the hazards increase in simple linear relation to the blood levels. They probably accelerate positively from some point. This probably also occurs with the adverse synergistic interac-

tion between nicotine and COHb on cardiac function (Aronow, 1976). It would, therefore, be reasonable to assume that the risks are probably increased far more than is indicated by simple comparison of blood levels. Furthermore, assessment of risk should not be confined to consideration of averages. Some individuals had exceptionally high blood nicotine and COHb levels after rapid smoking (Table 1). Subjects 2 and 14 had nicotine levels that were, respectively, 260% and 150% higher than their normal smoking level.

In a recent article, Horan, Linberg, and Hackett (1977) attempted to assess the extent to which nicotine poisoning occurs in rapid smoking. Most of their information was derived from an outdated edition of a well-known textbook of pharmacology (Goodman & Gilman, 3rd ed., 1965, rather than Goodman & Gilman, 5th ed. in 1975), and their article contains several errors and misinterpretations. They stated, for example, that a single cigarette yields about 6-8 mg of nicotine, yet the average nicotine yield of cigarettes smoked in the United States in 1975 was 1.2 mg, and the strongest brand on the market yielded only 2.1 mg (Owen, 1976). Even the hardest puffing smoker would find it difficult to abstract more than about three times the standard machine-smoked yield from a cigarette. Horan, Linberg, and Hackett also assumed that increasing the puff rate would proportionally increase the number of puffs, and hence the nicotine dose, obtained from a single cigarette (puff volume remaining the same). This is simply not true. It is doubtful whether a 10-fold increase in puff rate (from 1 per min in the case of standard machine smoking to 1 per 6 sec as in rapid smoking) would increase the number of puffs obtained from a cigarette by more than a factor of three. The average of 25 puffs per cigarette obtained by our subjects with rapid smoking represents a factor of approximately 2.5, and this was probably due more to a reduction in puff volume than the increase in puff rate. Horan, Linberg, and Hackett seemed not to appreciate that increases in puff rate produce higher levels of plasma nicotine (but not COHb), not so much by increasing the nicot-

tine dose per cigarette as by increasing the rate at which the dose is taken.

In our view, the incidence of cardiac complications is of greater significance than the occurrence of nicotine poisoning or intoxication. Nicotine intoxication per se is fairly rapidly reversible. Indeed, the pharmacological effects of nicotine that are evident in many smokers after normal smoking are manifestations of a degree of nicotine intoxication. So-called "green-tobacco sickness," an occupational illness of tobacco harvesters, is a form of nicotine intoxication due to absorption through the skin during tobacco cropping (Gehlbach et al., 1975). The symptoms include nausea, vomiting, dizziness, and prostration, far exceeding those usually encountered after rapid smoking. Mortality and long-term effects of green tobacco sickness have not been documented, but during the 1973 harvesting season an estimated 9% of North Carolina's 60,000 tobacco growers reported such illness among their workers (Gehlbach et al., 1975). As far as rapid smoking is concerned, the severity of manifest nicotine intoxication is relevant only insofar as it is an index of nicotine dosage, and hence the risk of serious cardiac complications that could persist after nicotine intoxication has passed. However, the relation of cardiac complications to signs of nicotine intoxication is unlikely to be very close. One reason is that the incidence of cardiac complications depends on the extent of underlying coronary heart disease. Another reason is that the tolerance mechanisms probably differ for the effects of nicotine on the brain as opposed to the heart and circulation. Finally, in our subjects the experience of nausea after rapid smoking was not significantly associated with high nicotine intake.

In view of the complexities, it is virtually impossible to make any meaningful quantitative estimate of the risks of rapid smoking on the basis of the blood level data alone. Since the main concern is for the cardiac complications, the most relevant approach to assessing the risks should certainly include careful electrocardiograph analysis during and after rapid smoking (Horan, Hackett, Nicholas, Linberg, Stone, & Lukaski, 1977). Ironically, though it is usual to make some esti-

mate of risk before widespread use of a new treatment approach, the most reassuring evidence of the relative safety of rapid smoking is its use for some years with "thousands of smokers" (Danaher et al., 1976) without apparent mishap.

The most careful screening cannot exclude the presence of even quite advanced coronary artery disease. Rapid smoking must, therefore, involve a greater risk to older subjects, 35 and up, especially if they are men. Besides careful screening, any risk of cardiac arrhythmia due to rapid smoking could be further reduced by the administration of a beta adrenergic blocker such as oxprenolol. This drug has been shown to reduce the increase in heart rate due to normal smoking (Carruthers, 1976). This approach might be especially relevant to those cases who are at greater risk but for whom it is particularly important to give up smoking.

As mentioned above, a degree of risk is more justified if rapid smoking can be shown to be the most likely way to enable a person to stop smoking. It was not the purpose of this article to evaluate rapid smoking as a treatment for smokers. Nevertheless, the fact that neither COHb increase during rapid smoking nor plasma nicotine levels after rapid smoking correlated significantly with reduction in cigarette consumption, on the one hand, or lowering of the desire to smoke, on the other (Table 2), suggests that excessive intake of nicotine and CO may not be necessary elements of any treatment effect. Furthermore, it seems that there is little to be gained by pressing subjects to undertake more than two rapid-smoking trials per session, since subjects who tolerate only two trials show, if anything, a greater reduction in both desire to smoke and cigarette consumption than do those who go on to a third trial. This is not explained by the possibility that heavier smokers might be more likely to tolerate three trials, since mean cigarette consumption did not differ significantly in the two groups ($t = 1.15$, ns). Of course, the possibility remains that two-trial subjects might have done better if pushed to do a third, or that three-trial subjects would have shown even less change after only two trials.

It could be argued that the lack of correla-

tion between early treatment outcome and nicotine and CO intake during rapid smoking was due to differences in individual tolerance. For example, a nicotine level of 30 ng/ml might be highly aversive to one subject but relative deprivation to another whose regular smoking level was around 50 ng/ml. However, this is an unlikely explanation, since the ratio of rapid-smoking to normal-smoking plasma nicotine level did not correlate significantly with reduction in desire to smoke after the session or with the reduction in cigarette consumption on the following day (Table 2).

Our data on heart rate increase (21% after the first trial and 19% after the second) show greater changes than the 9% increase reported by Hynd, O'Neal, and Severson (1976) but are in accord with the more substantial, controlled study by Danaher et al. (1976). A larger effect on heart rate could be expected when rapid smoking follows a period of abstinence.

It is concluded that rapid smoking can produce excessively high blood nicotine and COHb levels and that this constitutes a risk to all but the younger smoker. On the data available at present, the level of risk is impossible to calculate in quantitative terms. It could probably be reduced by a beta adrenergic blocking drug. Since excessive nicotine and CO intake may not be necessary for a treatment effect, it is suggested that the procedure could be made completely safe and possibly no less effective if subjects are instructed to take the smoke into the throat but to avoid inhaling it into the lungs, for it is only by inhalation that dangerously high levels are produced.

The Hand Dynamometer as a Neuropsychological Measure

Carl B. Dodrill

Department of Neurological Surgery
University of Washington School of Medicine

The sensitivity of the hand dynamometer to the presence of brain damage and to its lateralization was evaluated and compared with that of the Tapping Test and the Tactual Performance Test. Four groups of 25 subjects each were studied (control, right-hemisphere damage, left-hemisphere damage, and bilateral damage). Measures of performance on each test included those of each hand taken separately as well as their sum. To identify the lateralization of brain lesions, a method was developed that used the control group as a basis for comparison and that simultaneously considered the relative performances of each hand on each task. All test variables discriminated between the control and brain-damaged groups at high levels of statistical significance. Furthermore, the dynamometer discriminated between these groups as well as did the Tapping Test and Tactual Performance Test. Finally, the dynamometer correctly identified the lateralization of brain lesions in more instances than either of the other tests. It is concluded that the hand dynamometer is a neuropsychological measure of considerable promise.

Many years ago, Halstead (1947) demonstrated that assessment of voluntary motor movement could be useful in evaluating the integrity of brain functions using such measures as the Tapping Test and the Tactual Performance Test. Reitan (1966) expanded the use of these measures by demonstrating that differences in performance between the two hands are related to the relative functioning capabilities of the two cerebral hemispheres. Thus, by examining level of performance and by comparing the two sides of the body, these tests of motor speed and

agility were established as reliable indicators of the integrity of brain functions.

Clinicians have realized that intensity or strength of voluntary motor activity might also be a reliable indicator of brain functions, and many use some strength-of-grip measure in neuropsychological assessment. Such use has led to an establishment of its clinical value as well as to a listing of the dynamometer by Reitan and Davison (1974) as a neuropsychological measure. On a research basis, Reitan (1974) demonstrated that the strength of grip of young brain-damaged and nonneurological children (ages 5-8) differs only slightly. Boll (1974), in working with older children (ages 9-14), found much more striking differences. No parallel studies have been done with adults that have directly compared brain-damaged persons with nonneurological controls, and none have evaluated the dynamometer with respect to the correct placement of lateralized lesions. The present study addresses these areas and evaluates the utility of the hand dynamometer in comparison with two other better established neuropsychological measures (Tapping Test, Tactual Performance Test).

This project was supported by National Institutes of Health Contracts N01-NS-0-2281 and N01-NS-6-2341 and by National Institutes of Health Grant NS 04053 awarded by the National Institute of Neurological and Communicative Disorders and Stroke, U.S. Public Health Service, Department of Health, Education, and Welfare.

The author gratefully acknowledges the contribution of Ralph M. Reitan to this study by providing the data for the neurological groups.

Requests for reprints should be sent to Carl B. Dodrill, who is also at the Epilepsy Center (ZA-50), Harborview Medical Center, 325 Ninth Street, Seattle, Washington 98104.

Method

Subjects

Four groups of adults (ages 15 and over) were formed, with each group consisting of 25 persons. Subjects in the control group had negative neurological histories. They had never had any disease that might have affected the nervous system (meningitis, encephalitis, polio, diabetes, rheumatic fever, scarlet fever, etc.), and they had no histories of high fever, partial drowning, exposure to gas, heat exhaustion, fainting spells, or head trauma. They were recruited from a variety of community resources including churches, schools, and employment agencies.

Three groups of brain-damaged persons were selected on the basis of the primary location of brain damage (right hemisphere, left hemisphere, both cerebral hemispheres). In each group, there were 5 individuals with intrinsic brain tumors, 11 with a history of head trauma, and 9 with cerebral vascular problems. Neurological diagnoses were established by anamnestic information, angiography, pneumoencephalography, electroencephalography, skull x-rays, neurosurgical findings, and autopsy.

Across all groups, a subject-by-subject matching procedure was maintained for the variables of sex (there were 20 males and 5 females in each group), race (all subjects were Caucasian), and handedness (all subjects were right-handed). Within the brain-damaged groups, the subject-by-subject matching procedure included the general type of neurological difficulty (neoplastic, traumatic, vascular). Finally, within each set of 4 persons (1 from each group), matching was completed as closely as possible for age and years of formal education, with the result that each group averaged approximately 41.14 years of age and 10.68 years of education.

As part of their neuropsychological evaluations, all subjects were administered the dynamometer, the Tapping Test, and the Tactual Performance Test. Attention was given to the exact administrative procedures suggested by Reitan with a strong emphasis on maximal performance. To assess strength of grip, the Smedley Hand Dynamometer was used, which registers strength in kilograms. Two trials were given in alternating fashion for each hand and the beginning with the right (preferred) hand, and the average of the two trials was used as the final score for each hand.

Because the Tactual Performance Test provided a total time score summing all trials (including right hand, left hand, and both hands), summary scores (right plus left) for the Tapping Test and the dynamometer were also provided in addition to the usual scores for each hand alone.

Analyses

To evaluate the discriminability of the tests, univariate analyses of variance were run across all four groups for each test variable, and evaluations of significant differences between groups were assessed by the Newman-Keuls procedure (Winer,

1971). In these analyses, homogeneity of variance was maintained by converting all data to normalized standard scores with a mean of 50 and a standard deviation of 10. Performances on the Tactual Performance Test were considered on a minutes-per-block basis.

The effectiveness of each of the three tests in implicating lateralized damage was assessed using only the subjects with lateralized lesions. The performance by the left (nonpreferred) hand was divided by the performance of the right (preferred) hand so that in each instance a left-to-right comparison in performance could be made with a single score. The mean and standard deviation of this score for the control group were computed, and 1 standard deviation on either side of the mean was arbitrarily selected as the limit of normal performance. The performance of each individual in the right and left brain-damaged groups was then compared with this standard. If the performance for any brain-damaged patient on each of the three measures considered separately indicated that the right hand was not performing as well as would be expected in comparison with the performance of the left hand, the left cerebral hemisphere was considered to be implicated by that measure, and vice versa. Chi-square statistics were applied to the subjects who were classified by this procedure.

Results

The discriminability of each neuropsychological variable considered on a group-by-group basis is given in Table 1. Highly statistically significant differences across the groups were found with respect to every variable, and the control group did better than all brain-damaged groups in every instance. The dynamometer discriminated between the normal and brain-damaged groups as well as did either of the other tasks.

The lateralization data are presented in Table 2. If performance fell within the normal (1 standard deviation) range, neither hemisphere was considered implicated and placement was made in the "neither" group. When one hemisphere or the other was implicated, all three tests classified a majority of individuals correctly, and the dynamometer correctly classified the largest number.

Discussion

The high level of discriminability demonstrated by the dynamometer between normal and brain-damaged subjects was unexpected. It is true that the brain-damaged groups had

unequivocal evidence of cerebral involvement. It is also true that the nonneurological group, consisted of "off the street" individuals rather than the hospital populations usually studied (Halstead, 1947; Reitan, 1955; Vega & Parsons, 1967). These facts may have

Table 2
Numbers of Subjects in the Right- and Left-Damaged Groups Classified According to the Lateralizing Implications of Their Performance

served to accentuate the general differences between the groups, but they did not give the Tapping Test or the Tactual Performance Test any noticeable edge in discriminant ability over the dynamometer. This was particularly surprising in view of the extreme simplicity of the dynamometer. An incidental observation was that when performances by the preferred hand alone were considered, control subjects outperformed their matched brain-damaged subjects 91% of the time with the dynamometer, 82% of the time with the Tapping Test, and 84% of the time with the Tactual Performance Test. Thus, it appears that the dynamometer does effectively discriminate between normal and brain-damaged adults when consideration is made either on a subject-by-subject or on a group-by-group basis.

The discriminability of the dynamometer may in part relate to the age of the person to whom it is administered. It is of interest to note that Reitan (1974) showed only minimal discrimination between normal and brain-damaged young children with the dynamometer, but Boll (1974) showed better discrim-

inability consistent with that obtained with older children. The reasons for this are not clear, although it is possible that the test is most useful when a brain insult occurs well after the development of cerebral dominance.

The relatively good lateralization of lesions by the dynamometer was somewhat surprising. Admittedly, the criterion of 1 standard deviation above or below the control mean is arbitrary. Furthermore, it leads to findings that are, if anything, conservative in implicating one cerebral hemisphere or the other. For example, the performance by the control group with the left hand on the Tapping Test was approximately .93 that of the performance on the right hand. The standard deviation was .09, so that any score from .84 through 1.02 was considered within normal limits, whereas scores less than .84 implicated the right cerebral hemisphere and scores greater than 1.02 implicated the left cerebral hemisphere. If one assumes that a person's right (preferred) hand averages 50 on the Tapping Test, an identical performance by the left hand would fall in the range of normal limits, whereas clinical interpretation would definitely suggest that the right hand was slow. Furthermore, the score with the left hand would have to be 41 or less in order to implicate the right cerebral hemisphere, whereas in clinical practice scores of 42 or 43 would certainly raise the question of slowness with respect to the left hand. With the procedure being somewhat conservative, it is not surprising to discover that 42% to 58% of the people evaluated in the lateralization analysis (Table 2) had performances that implicated neither cerebral hemisphere on each test. However, the conservative and arbitrary nature of the procedure would not appear to favor any particular test and is not likely to account for the fact that when decisions were made, they were correct in 86% of the cases for the dynamometer and in 65% and 76% of the cases for the Tapping Test and the Tactual Performance Test, respectively.

The question can be raised as to whether or not a cutoff score should be established for the dynamometer in the same fashion that it has been established for the Halstead measures. This appears unwise, because (a) the

number of subjects in the present study is too small to constitute an adequate standardization sample, (b) there are obvious sex differences that would require separate norms, (c) certain vocational and avocational activities of individuals may affect scores on this test, and (d) the accuracy of the Smedley dynamometers depends on a spring that may become weakened with use and lead to error in measurement. Therefore, no effort has been made to establish a cutoff score.

Overall, the hand dynamometer both discriminates between normal and brain-damaged persons and lateralized lesions as well as do existing measures. It appears to be a promising neuropsychological measure that warrants both clinical use and further formal evaluation, especially in consideration of the brief administration time required vis-à-vis the other two neuropsychological measures (Tactual Performance Test, Tapping Test) conventionally used in the Halstead-Reitan battery.

An Initial Look at the Redundancy of Specialized MMPI Scales

James R. Clopton and Gary L. Klein
Texas Tech University

Numerous specialized Minnesota Multiphasic Personality Inventory (MMPI) scales have been developed despite speculation that the information provided by specialized scales replicates information that can be obtained from the 13 MMPI scales of the standard profile. In this study, scores of three specialized MMPI scales (the Prejudice scale, the Ego-Strength scale, and the MacAndrew Alcoholism scale) were found to be highly related to the scores of the standard MMPI scales. However, individual scores of the three specialized scales could not be accurately predicted from the standard scales. Furthermore, alcoholic and nonalcoholic psychiatric patients were more accurately identified by the 13 standard scales than by the MacAndrew Alcoholism scale.

The Minnesota Multiphasic Personality Inventory (MMPI) originally included three validity scales that assess test-taking attitudes and 10 clinical scales that identify common types of abnormal behavior. In addition to these 13 standard scales, numerous specialized MMPI scales have been constructed. Some of these specialized scales have been constructed to measure common personality dimensions such as dependency and prejudice. Other specialized MMPI scales have been developed to identify patterns of abnormal behavior, such as alcoholism, that are not assessed directly by any of the standard clinical scales. Interest in specialized scales has been increasing recently (Graham, 1978), and a number of specialized scales are routinely scored by automated MMPI interpretive systems.

The latest edition of the *MMPI Handbook* (Dahlstrom, Welsh, & Dahlstrom, 1975) listed 455 specialized scales that measure per-

sonality variables or identify patterns of abnormal behavior. Many of the specialized scales are too limited for widespread use, but the use of some specialized MMPI scales is quite common. Three specialized MMPI scales in common use are the Prejudice scale (Gough, 1956), the Ego-Strength scale (Baron, 1953), and the MacAndrew Alcoholism scale (MacAndrew, 1965). The Prejudice scale was designed originally to measure anti-Semitic prejudice, but it also appears to assess the broader trait of rigidity in thinking. The Ego-Strength scale is frequently used to help predict the likelihood that a person will profit from receiving psychotherapy. The MacAndrew scale has been shown to differentiate between alcoholic and nonalcoholic patients in a variety of treatment settings.

Despite the attractiveness of developing new MMPI scales for specialized tasks and the popularity of some specialized MMPI scales, there are serious questions regarding the use of specialized MMPI scales. One basic question concerns the possible redundancy or superfluity of the information provided by the specialized scales. Caldwell (Note 1) asserted that he could predict many specialized scale scores so well from the scores of the 13 standard MMPI scales that the specialized scales did not appear to provide any information beyond that which

Predicted	Female	85	21.84	3.20	14.47-31.83			60.0

Note. The accuracy of the predicted scores is the percentage of subjects whose observed scale score was within the 95% confidence limits of the value predicted from the regression equation.

* $p < .0001$.

could be provided by the standard scales. Unfortunately, Caldwell's data have not been published, and other data regarding the possible redundancy of specialized MMPI scales are lacking.

Method

MMPI data were obtained from 197 psychiatric patients and from 170 male applicants for jobs with police and fire departments. The psychiatric patients and job applicants have been evaluated at a regional mental health center during the last 7 years. MMPI data from the psychiatric patients were used to investigate the clinically oriented Ego-Strength and MacAndrew scales. MMPI data from the job applicants seemed more appropriate for an investigation of the nonclinical Prejudice scale.

Regression analysis was used to determine how well subjects' specialized scale scores could have been predicted from their scores on the 13 standard MMPI scales. For the Ego-Strength scale and the MacAndrew scale, separate analyses were performed for male ($n = 112$) and female ($n = 85$) psychiatric patients.

A review of the psychiatric patients' records revealed that 48 patients (24.4%) had difficulties directly related to alcohol abuse. Discriminant analysis was used to determine whether alcoholic and nonalcoholic patients are more accurately identified by the MacAndrew scale or by the 13 standard MMPI scales.

Results

Table 1 presents the results of the regression analyses. The observed scores for all

three specialized scales were significantly related to the scores of the 13 standard scales, and a large portion of the variance in each of the specialized scales was accounted for by the 13 standard scale scores.

The regression equations were used to derive predicted specialized scale scores for subjects. It was then determined, for each of the three specialized scales, whether each observed scale score was within the 95% confidence limits of the predicted score. Approximately 60% of the predicted scores for the Ego-Strength and MacAndrew scales were found to be accurate by this criterion (see Table 1). For the Prejudice scale, 45.3% of the predicted scores were accurate. Thus, many of the individual scores of the three specialized scales could not be accurately predicted from the standard scale scores.

A ready explanation for the inaccurate predictions of the specialized scale scores is that the variance among the observed scores of each specialized scale was underestimated by the predicted scores (see Table 1). Imperfect multiple correlation ($1.00 > R > -1.00$) and use of a regression equation with a least-squares prediction rule assured the reduced variance among the predicted scores (Hays, 1963, pp. 500-501). As a consequence of the underestimation of the variance in specialized scale scores, prediction was most accurate

for scores close to the mean scale score, and the prediction became increasingly less accurate as the scores departed from the mean.

The discriminant analysis with the 13 standard MMPI scales as predictors correctly classified all of the female psychiatric patients as alcoholic or nonalcoholic and correctly classified 91.1% of the male patients (85.3% of the male alcoholics and 93.6% of the male nonalcoholic patients). In contrast, the discriminant analysis using the MacAndrew scale as the predictor correctly classified most of the nonalcoholic patients (100% of the female nonalcoholic patients and 89.7% of the male nonalcoholic patients), but it identified few of the alcoholic patients (7.1% of the female alcoholic patients and 35.3% of the male alcoholic patients). The optimal cutoff score for the MacAndrew scale (the scale score that would most correctly classify patients) was 27 for female patients and 25 for male patients.

Discussion

In this study an attempt was made to predict the scores of three specialized MMPI scales from the scores of the 13 standard MMPI scales. The three specialized MMPI scales were found to be highly related to the 13 MMPI scales of the standard profile, but individual scores on the three specialized scales could not be accurately predicted from standard scale scores. The three specialized scales examined in this study appear to provide information not available from the standard MMPI scales.

Extreme scores on the MMPI scales are often the scores of most importance in a clinical setting. In this study the prediction of specialized MMPI scale scores became increasingly less accurate as the scores departed from the mean. However, this inaccurate prediction of extreme specialized scale scores should not be interpreted as an indication that predictions from specialized scales are superior to predictions from the standard scales. The more extreme the scale score, the larger the error of measurement it probably contains. From this perspective, the most extreme specialized scale scores are also the

least reliable, and, consequently, it is unrealistic to expect highly accurate predictions of extreme specialized scale scores.

In this study, the 13 standard scales were more accurate than the MacAndrew scale in identifying psychiatric patients who abused alcohol. Future research should seek to determine, for other specialized scales, whether specialized scale scores or the standard scale scores are more closely related to external criteria (independent measures of relevant personality variables or patterns of abnormal behavior). For example, a comparison could be made of the predictions of successful outcome in psychotherapy by the Ego-Strength scale and by the 13 scales of the standard MMPI profile. It is not possible to anticipate the outcome of such comparisons from the finding that specialized scale scores cannot be accurately predicted from the standard MMPI scales.

Effects of a Self-Control Manual, Rapid Smoking, and Amount of Therapist Contact on Smoking Reduction

Russell E. Glasgow
North Dakota State University

This study evaluated a self-help treatment manual consisting of stimulus control, rapid smoking, and coping relaxation techniques. Sixty-nine subjects who smoked at least 20 cigarettes per day were randomly assigned to (a) a self-help manual with minimal (two sessions) therapist contact, (b) a self-help manual with high (seven sessions) therapist contact, (c) a high-therapist-contact rapid smoking condition, or to (d) a high-therapist-contact normal-paced smoking condition. Results indicate that while the overall program was moderately effective, groups did not differ on percentage of baseline smoking or on number of subjects abstinent at posttreatment, 3-month, or 6-month follow-up. Informant reports of subjects' smoking behavior and carbon monoxide analyses of expired air samples confirmed these findings. Subjects in the minimal contact condition generally followed through on their programs, required less therapist time, and were at least as successful as those in other groups in terms of long-term results. The implications of these findings for self-help manuals for smoking reduction are discussed.

Since the Surgeon General's report on the health effects of cigarette smoking in 1963, there have been numerous evaluations of smoking reduction programs. Reviews of this literature (Bernstein, 1969; Lichtenstein & Keutzer, 1971; Schwartz, 1969) have concluded that with few exceptions, the long-term effects of these studies have been disappointing. The typical result has been short-term reduction to 10%-40% of baseline, with relapse to approximately 75% of baseline at a 4- to 6-month follow-up (McFall & Hammen, 1971). A more recent evaluation

(Hunt & Belpaer, 1974) found that initial decreases in smoking frequency generally dissipate rapidly and asymptote around 60% of baseline rate. These authors also noted that on the average only 20%-30% of those subjects abstinent at termination were still not smoking at follow-up. In light of these findings, recent reviews (Bernstein & Glasgow, in press; Bernstein & McAlister, 1976; Lichtenstein & Danaher, 1976; Schwartz, 1977) have suggested that investigators focus on ways to maintain initial treatment effects.

One attempted solution to the maintenance problem has involved the use of multicomponent self-help treatment manuals. There are several potential advantages to such programs. By playing a more active role in a program, clients may learn skills and treatment techniques more thoroughly. With self-help programs there is a less abrupt transition period when treatment ends than with therapist-administered programs, and clients have their manuals to refer to if maintenance problems arise. It has also been hypothesized that client-directed treatments might lead to greater maintenance of therapeutic gains than

This report is based on a doctoral dissertation submitted to the Department of Psychology, University of Oregon. Appreciation is expressed to committee members David Campbell, Gerald Rosen, Herbert Severson, and especially Edward Lichtenstein, committee chairman. Nicole Barde, Sharon Brazil, Chris Clarke, Suzanne Dieringer, Bruce Fitzgerald, Gerald Gay, Cathy Hanauska, and John Piel served ably as therapists and research assistants. Thanks are also due Gerald Boyem and the Lane County Regional Air Pollution Authority for their kind analysis of the expired air samples.

therapist-directed programs by producing more internal attributions of success (Kopel & Arkowitz, 1975). Although a number of studies have been conducted in this area (Conway, 1977; Danaher, 1977; Harris & Rothburg, 1972; Ober, 1968; Winet, 1973; Brengelman, Note 1; Conway & Morton, Note 2; Danaher & Lichtenstein, Note 3; Pechacek, Note 4), self-help manuals have generally not been found effective (Glasgow & Rosen, 1978). A possible explanation for this situation is that investigators may have sacrificed quality for quantity. Most manuals contain a smorgasbord of procedures including self-monitoring and hierarchical reduction; stimulus control suggestions; self-reward, self-punishment, and behavioral contracting strategies; aversive smoking techniques; thought stopping or other cognitive interventions; information on the hazards of smoking and reasons for not smoking; suggestions for alternative behaviors incompatible with smoking, and so forth. Subjects are generally not given explicit instructions on how to implement these strategies. Consequently, subjects may not learn any of the techniques well enough to use them effectively once treatment has terminated.

The main purpose of this investigation was to evaluate the efficacy of a self-help smoking reduction manual that presented in depth a few promising techniques in an organized, sequential manner. The manual included stimulus control, rapid smoking, and coping relaxation techniques.

Stimulus control procedures have been found effective in reducing smoking until one reaches the level of 10–12 cigarettes per day (Marston & McFall, 1971; Sachs, Bean, & Morrow, 1970). In the present study stimulus control techniques were used as an initial component to assist in reduction of smoking levels and to teach subjects a behavioral problem-solving strategy. Rapid smoking has generally been found to be the single most effective cessation technique developed to date (Danaher, *in press*; Lichtenstein, Harris, Birchler, Wahl, & Schmahl, 1973; Schmahl, Lichtenstein, & Harris, 1972). It was included as a way to produce initial cessation and to get subjects to devalue the act of smoking. The relaxation procedure was in-

cluded as a coping skills technique (Goldfried & Trier, 1974) to provide an alternative response to smoking when subjects experienced a craving for a cigarette.

Another potential advantage of self-help treatment manuals is substantial savings in terms of therapist time. Survey data have indicated that many persons wishing to stop smoking would not attend a smoking clinic but would use a manual (McAlister, 1975). Thus, many more clients than are currently seen by therapists could be treated at a greatly reduced cost. Although several smoking manuals exist (Glasgow & Rosen, 1978), few of them have been tested under self-administered or minimal therapist contact conditions. Brengelman (Note 1) has tested a manual that was mailed to participants. Initial reports of abstinence were impressive, but the manual did not appear to have been compared to therapist-administered treatments or control conditions. Danaher and Lichtenstein (Note 3) reported less encouraging results for coverant control treatment manuals administered under minimal contact conditions.

The self-control manual was tested under two levels of therapist contact. Therapist-administered rapid smoking and a normal-paced smoking condition were also included as "component control groups" against which to evaluate the manual, thus yielding four treatment groups. Self-monitored frequency of smoking was recorded throughout treatment and at a 3-month follow-up. A 6-month phone call follow-up provided a further estimate of long-term effects. Carbon monoxide analyses of expired air samples and informant reports of smoking provided additional indices of smoking behavior. Process measures included subjects' therapeutic expectancies, amount of therapist contact time, indices of how well subjects carried out assignments (follow through), and ratings of the unpleasantness of aversive smoking sessions.

Method

Subjects

Smokers were solicited through local media announcements of a smoking reduction program. Selection criteria included smoking at least a pack a

day; informed consent; and payment of a \$20 deposit, \$15 of which was refundable on completion of the project. Applicants with a history of cardiovascular or chronic respiratory problems (8.9% of those contacting the clinic) were excluded. Subjects meeting the above screening criteria were required to obtain their physician's consent before beginning the program. Of those seeking physician approval, 8.1% were denied, most often due to pregnancy.

Sixty-two smokers, 32 men and 30 women, comprised the final sample. They averaged 32.6 years of age, estimated their baseline smoking rate at 31.0 cigarettes per day, had a self-monitored baseline of 24.7 cigarettes per day, and had smoked for an average of 15.1 years.

Therapists

Therapists were three male and three female undergraduate psychology majors. Therapists received extensive training over a 2-month period prior to the study. Training involved reading relevant background material, observing demonstrations of procedures, using role-playing techniques in the various groups, and seeing at least one pilot case. Treatment was standardized across therapists by means of procedural outlines for each session. Adherence to therapeutic procedures was further ensured by weekly group meetings and individual feedback from the project supervisor, who observed sessions or listened to audiotapes of a majority of the sessions. Therapists saw approximately an equal number of male and female subjects in each treatment condition.

Procedure

Subjects were given a general description of the program and were informed of the selection criteria over the telephone. Interested subjects were then randomly assigned to one of four treatment groups. Following an individual intake session, subjects began monitoring their cigarette consumption. After a 1-week baseline, subjects met individually with their assigned therapist for their respective 3-week treatment programs.

Treatment Groups

Minimal contact self-control ($n = 15$). This group received a 37-page manual detailing a multi-component treatment program for nonsmoking (Glasgow, Lichtenstein, & Danaher, Note 5). The manual presented a behavioral analysis of smoking and emphasized the importance of recording and counteracting smoking urges. Initial chapters focused on training in progressive relaxation and stimulus control techniques for hierarchical reduction. A three-phase relaxation training program presented relaxation as a coping strategy for use when experiencing urges to smoke.

The rapid smoking procedure closely followed that described by Kopel (1975). One trial consisted of

puffing on a cigarette every 6 sec until the subject could not bear to continue or until 10 min had elapsed, whichever came first. Immediately after each trial subjects completed a checklist of possible negative sensations (Glasgow, 1977). After a 2- to 4-min rest period, subjects underwent a second trial identical to the first, with the exception of a 5-min time limit. There were six such sessions consisting of two trials each. Sessions were held on the 1st, 2nd, 4th, 7th, and 10th days after the initial session.

Subjects' progress through the manual and completion of relaxation and rapid smoking sessions were recorded on a progress schedule contained in the manual. Subjects in the minimal contact group initially met with a therapist to receive their manual, a rationale for the program, and a demonstration of relaxation procedures. They then worked on their own, meeting once more with their therapist midway through the program to receive their first rapid smoking session. Subsequent rapid smoking and relaxation sessions were self-administered by clients at home. Therapists called weekly to check on subjects' progress and to answer questions.

High contact self-control ($n = 15$). This group received the same manual as the minimal contact group but had regular meetings with a therapist. Subjects were assigned to read a section of the manual and then met with their therapist to implement the assignments in that section. Seven meetings were held over the 3-week treatment period. Subjects received more direction from therapists on relaxation and stimulus control procedures than did minimal contact subjects, but rapid smoking and relaxation sessions were held at home after initial demonstrations. Treatment techniques and the sequence of components were identical to those of the minimal contact group.

High contact rapid smoking ($n = 16$). This group was intended as a replication of clinic-administered rapid smoking as used in previous research. The procedure and spacing of rapid smoking were identical to that for the manual groups, but all sessions were therapist administered. There was a 9-day "preparation period" after an initial meeting for subjects in this group before beginning rapid smoking. This was to insure that all groups completed treatment at the same time. Flaxman (1978) found that such a waiting period before a "target date" for beginning rapid smoking was more effective than beginning rapid smoking immediately.

High contact normal-paced smoking ($n = 16$). This group received an "aversive smoking" procedure used in previous research (Danaher, 1977; Kopel, 1975; Lichtenstein et al., 1973) to control for non-specific treatment effects. It involved smoking at one's normal rate while focusing on the unpleasant aspects of the pure smoking experience. Subjects were instructed to smoke until they could not bear to continue or until 5 min had elapsed, whichever came first. Otherwise, the rationale, number and spacing of sessions, and procedures used were identical to those of the rapid smoking group. If subjects smoked faster than one puff every 15-20 sec, they were reminded to smoke at their normal rate.

Measures

Subjects' therapeutic expectancies were assessed after the first treatment session and midway through the program following the first rapid smoking or normal-paced aversive smoking session. Monitoring of number of cigarettes smoked continued throughout treatment and during the week after treatment ended. Subjects again monitored their smoking for a 1-week period 3 months after treatment had ended and were then scheduled for a final interview. At this meeting deposits were returned and unannounced breath samples were collected. Expired air samples, which were analyzed for carbon monoxide (CO) content, were collected to provide an objective index of recent smoking behavior (Danaher, Lichtenstein, & Sullivan, 1976; Lando, 1975; Kopel, Note 6). Details of the collection procedure are available in Glasgow (1978). Informant reports of smoking were obtained by mailing informants a one-page questionnaire that asked for estimates of subjects' recent smoking behavior. Information on smoking rates 6 months after treatment ended was obtained by telephone calls asking for subjects' estimates of their average daily cigarette consumption during the preceding week.

Results

Of the 69 subjects beginning the program, 62 completed treatment. Five subjects dropped out after the first session for reasons unrelated to treatment, 1 subject dropped out after the fourth session following her doctor's advice when she found out that she was pregnant, and 1 subject in the normal-paced group dropped out after four sessions

apparently because she was not helped by the program. Three-month follow-up information was obtained on 61 of the subjects.

Preliminary Analyses

One-way analyses of variance revealed no significant differences between treatment groups on demographic indices, smoking history variables, or baseline smoking rates. There were no between-groups differences on expectancy of success, either after the first treatment session or after the first aversive smoking session. All groups indicated moderate to extreme confidence in their ability to stop smoking in their program.

Measures taken from the negative sensations checklist completed during aversive sessions revealed significant between-groups differences (see Table 1) on average number of cigarettes smoked, number of negative sensations endorsed, and aversiveness ratings for both the first and second trials (averaged across sessions). Groups also differed on length of trial for the first trial only. Planned comparisons indicated that rapid smoking was significantly more intense (i.e., more cigarettes smoked, more sensations endorsed) than the normal-paced procedure on each of these measures. The normal-paced group smoked at an average rate of 1 puff every 24.2 sec, compared to the 6-sec pace set for rapid smoking groups.

Table 1

Treatment Group Means on Process Measures for Trials 1 and 2 Collapsed Across Sessions

Measure	Manual				Aversive smoking only

^a In minutes; between-groups differences significant at the .001 level.

Follow-through measures indicated that subjects in all groups completed most of their programs. Three measures of completion of homework assignments for subjects receiving the manual were obtained from entries in the progress sheet in the front of subject's manuals. Subjects averaged 93% completion of reading assignments, 95% completion of relaxation practice sessions, and 90% completion of aversive smoking sessions. There were no significant differences on follow-through measures between the minimal contact group and the high contact group. Subjects receiving clinic-administered rapid smoking and normal-paced smoking completed 100% and 94% of their aversive sessions, respectively.

Effectiveness and Efficiency of Treatments

Percentage of baseline smoking averaged across treatment groups was 16.7% (3.4 cigarettes per day) during the week after treatment, and 40% of subjects were completely abstinent. At the 3-month follow-up, subjects averaged 54.7% of baseline (12.4 cigarettes per day), and 28% were not smoking. Correlated *t* tests revealed a significant decrease in smoking rate across groups from baseline to posttreatment, $t(61) = 13.29$, $p < .001$. Even though subjects were still smoking significantly less at the 3-month follow-up than they had at baseline, $t(60) = 7.03$, $p < .001$, they were smoking significantly more than they had at posttreatment, $t(60) = 6.42$, $p < .001$.

Between-groups differences on number of cigarettes smoked, percentage of baseline smoking, and number of subjects abstinent failed to reach significance either at post-treatment or at the 3-month follow-up. The pattern of treatment means (see Table 2) suggested that rapid smoking alone was somewhat more effective than the other treatments at the end of the program, but the great variability in the data appears to have precluded between-group differences. By follow-up the situation had reversed itself, with the manual groups being somewhat superior to other conditions. Again, effects were much too variable to obtain significance. Analyses of CO concentrations and informant reports of smoking similarly failed to reveal significant between-groups differences.

It was possible to contact 50 of the 62 subjects for the 6-month phone contact. At this point in time, subjects reported averaging 70.4% of their baseline smoking rate. Only 16% of those contacted reported being abstinent. The trend for manual groups ($M_s = 66.9\%$ and 64% of baseline for minimal and high contact groups, respectively) to be slightly superior to control groups ($M_s = 80.1\%$ and 67.8% for rapid smoking and normal-paced smoking, respectively) continued, but it again failed to approach significance on any outcome measure.

Efficiency was indexed by computing amount of therapist time spent in contact with clients from progress reports completed by therapists immediately after each session. There was a highly significant effect on this

measure, $F(3, 58) = 30.4$, $p < .001$. Tukey post hoc tests (Winer, 1971) revealed that the minimal contact manual group was more efficient than all other treatments and that the normal-paced group required less therapist time than did the high contact manual group. The minimal contact group required an average of approximately $1\frac{1}{2}$ hours (including telephone calls) of therapist contact, slightly more than half the time required by other groups (see Table 2).

Relationships Between Measures

The Pearson product-moment correlation between CO concentrations and self-report of cigarettes smoked that day was .40 ($p < .05$). The correlation between subjects' report of time elapsed since they smoked their last cigarette and CO levels was $-.62$ ($p < .001$). A t test comparing abstinent and smoking subjects on CO levels was highly significant, $t(53) = 4.89$, $p < .001$. Mean CO levels were 29.9 parts per million (ppm) for smokers and 10.4 ppm for nonsmokers. Informant reports of subjects' smoking were obtained on 57 of the 62 subjects. Twenty-one subjects reported abstinence when their informants were contacted, and all of these reports were confirmed by informants.

In a search for predictors of treatment success, numerous demographic, smoking history, and process measures were correlated with outcome at posttreatment and follow-up. The only variable found to be consistently related to outcome was the expectancy rating immediately after the first aversive smoking session. This rating was modestly correlated with percentage of baseline smoking at posttreatment ($r = -.37$, $p < .01$) and at the 3-month follow-up ($r = -.26$, $p < .05$). Posttreatment smoking rates were moderately correlated with follow-up smoking rates ($r_s = .38$ and $.47$ for number of cigarettes and percentage of baseline, respectively).

Discussion

The overall magnitude of observed change was somewhat better than has typically been reported in the smoking literature (Hunt & Bespalec, 1974; McFall & Hammen, 1971)

but was less impressive than most previous investigations of rapid smoking (Lichtenstein et al., 1973; Harris & Lichtenstein, Note 7; Weinrobe & Lichtenstein, Note 8). There are several possible explanations for this result. The present investigation used undergraduate paraprofessional therapists, and it is possible that this led to diminished effectiveness. However, this is unlikely, as Weinrobe and Lichtenstein (Note 8) have successfully used paraprofessionals as rapid smoking therapists. Also, one of the more experienced therapists in the present study had previously served in studies that had produced more impressive absolute results. Analyses revealed that this therapist was no more successful than other therapists in the investigation.

A fixed number of rapid smoking sessions and trials per session were used rather than continuing until subjects reported abstinence as in earlier research. While offering greater experimental control, the standardized approach likely reduces the clinical impact of treatment. Other recent studies using rapid smoking with a fixed number of sessions have generally reported absolute results similar to those of this study (see Danaher, in press) in contrast to the more impressive earlier results. Investigations of the effects of varying termination criteria (e.g., Weinrobe & Lichtenstein, Note 8) deserve further attention.

The main factor militating against significant results in this investigation was the enormous within-group variability observed. This is a common finding in smoking reduction outcome studies (Bernstein & Glasgow, in press; Lichtenstein & Danaher, 1976) and suggests the need for identifying predictors of success for different treatments. Consistent with past research, the present study was relatively unsuccessful in identifying demographic or smoking history variables that correlate with the outcome of standardized programs. It is suggested that future research should pursue the alternative strategy of evaluating different methods of individualizing treatment programs. Investigators using the locus of control scale (Rotter, 1966) have been moderately successful in assigning

subjects to appropriate smoking reduction programs (Best, 1975). It is possible that a recent extension of the internal-external locus of control dimension to the specific area of health (Wallston, Wallston, Kaplan, & Maides, 1976) would be even more effective in tailoring treatments to subjects.

It may be that features in the design of the manual reduced its effectiveness. One possibility is that portions of the manual may have been too demanding or complicated. Even though the program was restricted to a few techniques, these were covered in detail, and subjects may not have been provided with sufficient time to learn them adequately. The process of identifying effective (and ineffective) techniques in multicomponent treatment programs remains a complicated but important task for future research.

This study is consistent with numerous other investigations in finding only short-term (Winet, 1973; Conway & Morton, Note 2) or no beneficial effects (Conway, 1977; Danaher, 1977; Ober, 1968; Danaher & Lichtenstein, Note 3) from manuals. It must be concluded that at the present time effective self-help manuals for smoking reduction do not exist. It is suggested that authors concentrate on evaluating alternative treatment approaches before rushing to publish unvalidated programs. It may be that there is an addictive component of smoking—likely associated with nicotine (Russell, 1974; Schacter et al., 1977)—that is resistant to self-control approaches. Possible alternative strategies would be to establish a goal of controlled smoking (Frederiksen & Petersen, Note 9) rather than complete cessation or the use of nicotine chewing gum as a supplement to smoking manuals.

Despite its failure to improve treatment success, the minimal contact self-help manual condition was very efficient and produced long-term results at least as good as those of clinic-based treatment conditions. Unlike many other studies on self-help manuals (Glasgow & Rosen, 1978), minimal contact subjects completed the great majority of their programs. The high follow-through percentages in this program may be attributable

to the progress chart in the manual, which specified the schedule that subjects should adhere to in completing their programs. The results of the present study suggest that if an effective smoking reduction manual were developed, evaluation under minimal contact or self-administered conditions would be warranted.

The failure of rapid smoking to produce results superior to those of the control group is somewhat puzzling in light of previous investigations using similar groups (Danaher, 1977; Kopel, 1975; Lichtenstein et al., 1973). This result appears to be a combined effect of rapid smoking being less effective and the normal-paced procedure being more effective (at follow-up) than in other studies. Process measures indicated that rapid smoking was more intense and aversive than normal-paced smoking, thus suggesting that the treatments did differ procedurally. The relatively good long-term performance of what was intended as a control group, along with the failure of process measures taken during aversive sessions to correlate with outcome, suggests that the normal-paced procedure may be better construed as an alternative treatment than as a control group. Its use might be recommended in cases in which rapid smoking is contraindicated (Lichtenstein & Glasgow, 1977).

Delinquent behavior is conceptualized as a manifestation of situation-specific social-behavioral skill deficits. The research was in two phases. In Phase 1, a measure consisting of 44 behavioral role-playing and problem-solving items—the Adolescent Problems Inventory (API)—was empirically developed, along with an item-specific criterion-referenced raters' manual. The inventory was designed to identify strengths and weaknesses in the personal and interpersonal skills repertoires of adolescent boys. Phase 2 was concerned with the validation of the API. In an initial validation study, the API responses of institutionalized delinquent boys were rated as less competent than the responses of either of two nondelinquent groups of teenage boys ("good citizens" and "leaders") from a public high school. Analyses of the inventory's characteristics showed it to be reliable, to be composed of items with little or no cluster structure, and to have extraordinary discriminant power. A second validation study compared the API responses of two groups: institutionalized delinquent boys who had frequent behavioral problems within the institution and institutionalized delinquent boys who had few acting-out problems within the institution. The former group was judged to respond less skillfully. A third validation study replicated previous group differences between delinquents and carefully matched nondelinquents. The study also showed that the type of directions given ("What would you do?" vs. "What is the best thing to do?") and test format (free response vs. multiple choice) significantly affected performance. It is suggested that researchers using a social skills conceptualization of personality do more thorough assessment studies of behavior pathologies before embarking on the development of large-scale social skills training programs.

It has been suggested that some individuals behave maladaptively simply because they lack the requisite skills to do better (e.g., McFall, 1976). In recent years, this skill-deficit conception of deviance has been reflected in numerous experimental skill-training programs aimed at treating such clinical populations as nonassertive college students (McFall & Twentymen, 1973), shy males (Twentymen & McFall, 1975), alcoholics (Sobell & Sobell, 1973), psychiatric inpatients (Goldsmith & McFall, 1975), and

male adolescent delinquents (Sarason & Ganzer, 1971).

Unfortunately, nearly all skill-training studies to date have been treatment oriented; that is, they have been concerned either with evaluating the general therapeutic utility of skill-training programs or with assessing the specific contributions of various training components, such as instructions, modeling, rehearsal, or feedback. Meanwhile, many fundamental questions concerning the underlying assumptions, concepts, and methods of the

skill-training approach have been ignored. Some investigators, for example, have developed the content of their skill-training programs without first conducting a thorough and systematic analysis of the performance problems supposedly addressed by the programs. As a result, they have had no way of knowing whether their programs actually focused on the most relevant problem situations for their clients or whether the behaviors taught in the programs represented genuine solutions to these target problems. Furthermore, some investigators have offered skill training without first establishing that their clients actually were deficient in the particular skills being taught.

What is needed at this point is research aimed at developing a taxonomy of the particular problem situations and skill deficits most characteristic of particular clinical populations. In the absence of such basic research, it will be difficult to develop valid methods for assessing and classifying the skill deficits of individual clients, and it will be difficult to determine what new behaviors clients need to acquire in order to perform more competently. Clearly, basic taxonomic research is a prerequisite to further treatment-oriented research.

The present research was based on a social-skills conception of delinquency among adolescent boys. Specifically, it was hypothesized that boys who have gotten into trouble with the law (i.e., adjudicated delinquents) would show situation-specific skill deficits when their performance in selected tasks was compared to that of matched nondelinquent

boys. The research was conducted in two phases. The first was concerned with identifying problem situations facing today's teenagers that might differentiate between the performance skills of delinquent and nondelinquent boys and, concomitantly, with developing explicit situation-specific criteria for evaluating performance competence. The first phase culminated in the creation of a behavioral role-playing measure of social skills, the Adolescent Problems Inventory (API). The second phase was concerned with validating the API by empirically evaluating its ability to differentiate between delinquent and nondelinquent boys. By implication, this phase also represented an indirect test of the utility of the underlying social-skills conception of delinquency. Although the research did not involve any treatment efforts, one of its long-term aims was to provide a solid foundation on which to build future skill-training programs.

Development of the Adolescent Problems Inventory

The procedures for the first phase were adapted from Goldfried and D'Zurilla's (1969) guidelines for the behavioral analysis of social competence. There were five sequential steps: (a) situational analysis, (b) item development, (c) response enumeration, (d) response evaluation, and (e) construction of the inventory and rater's manual. The purpose, procedures, and products of each step were as follows:

Situational analysis. The first step involved the identification of problem situations that might be related to delinquency. Initially, a large pool of promising situations was gleaned from a variety of sources: the sociological and psychological literature on the etiology of delinquency; case files of institutionalized delinquents; structured interviews with nondelinquent boys (ages 15-17); interviews with correctional psychologists, social workers, youth counselors, and teachers; and an open-ended questionnaire, given to 22 institutionalized delinquent boys (ages 14-18, $M = 15.8$, $SD = 1.2$), that asked about the problems of today's teenagers. This initial pool of situations subse-

The authors gratefully acknowledge the Wisconsin Division of Corrections and the Madison Public Schools for their support of the research project. They also wish to extend their thanks to Judith Rosenberg, who served as experimenter and data analyst for the second validation study. Barbara Freedman developed the Adolescent Problems Inventory and conducted the first two validation studies as part of her doctoral research. Lisa Rosenthal carried out Study 3 as part of her master's research. Pete Donahoe and David Schlundt performed extensive subsequent analyses of the data and assisted in the preparation of the manuscript. Richard McFall supervised the overall project. Requests for reprints should be sent to Barbara J. Freedman, Bureau of Program Resources, Division of Corrections, Box 669, Madison, Wisconsin 53701.

quently was reduced to a sample of 51 general descriptions of common problem situations; this reduction was achieved by eliminating redundancies, by condensing similar situations into a single version, and by excluding situations that seemed unrelated to social skills.

The ultimate aim was to develop an inventory not a scale. If we had been developing a scale, we probably would have selected maximally similar or highly-related items from among a pool of items assumed to represent a common domain, factor, or attribute. Since we were developing an inventory, however, we tried to select maximally dissimilar, nonoverlapping items. In addition, we did not assume the existence of any underlying factors, domains, or general attributes. We assumed only that the items had two things in common: (a) They were descriptive of problem situations with which many teenage boys are familiar, and (b) the problem situations were ones that if mishandled could get a teenage boy into trouble—conceivably into legal trouble. Thus, the assumed relationship between inventory performance and delinquency was essentially one of risk. The more frequently a teenager handles problem situations competently, the less likely he will get into trouble and be judged a delinquent.

The more universal and difficult a particular situation, the more appropriate it was considered to be for the purposes of the present research. Therefore, each of the 51 situations was rated on two 4-point scales by a new sample of 22 institutionalized delinquent boys (ages 14–18, $M = 15.8$, $SD = 1.2$). The first scale assessed how “common” they felt the situation was for boys their age; the second scale assessed how “difficult” they thought the situation would be for them to handle. A composite index of these common and difficulty ratings was constructed, and the 51 situations were rank ordered on that index to determine their appropriateness for inclusion in the study. Based on this ranking, nine situations were eliminated for being too uncommon or too easy, leaving a final pool of 42 problem situations.

Item development. The purpose of this second step was to translate the 42 general problem descriptions into specific items suit-

able for use as stimuli in a behavioral role-playing test. Ninety potential test items were written in the format of narrative descriptions in which the scene, characters, history, and goals of each incident were presented. At the end of each item, adolescents were asked to indicate how they would respond if they found themselves facing such a problem. The particular question posed to respondents took one of the two forms, depending on the particular item: (a) “What would you say or do now?” or (b) “What can you do to go about resolving this problem?” The following are examples of the two types of items: ¹

You're visiting your aunt in another part of town, and you don't know any of the guys your age there. You're walking along her street, and some guy is walking toward you. He is about your size. As he is about to pass you, he deliberately bumps into you, and you nearly lose your balance. What do you say or do now?

It is Saturday morning, and you have nothing planned for the whole day. There's nothing to look forward to all day. You feel bored already, just thinking about it. You need some kicks. What can you do to go about solving this problem?

Some items posed isolated problems, whereas other items posed related or sequential problems. For instance, the example in which the respondent was bumped into by a stranger was followed by this related item:

Now what if he had done the same thing, bumped into you, and you nearly lost your balance, and this time he said, “Look where you're going, clumsy!” What do you say or do now?

Response enumeration. The next step was to obtain a sample of possible responses, representing a wide range of social competency, to each of the 90 items. Twenty-three subjects participated in this step. There were 12 institutionalized delinquent boys (M age = 16.2, $SD = 1.0$); 6 nondelinquent boys from public and parochial high schools (M age = 16.9, $SD = .9$); and 5 adults (4 men, 1 woman) with professional experience in working with delinquent boys.

¹ Copies of all 90 items are available on request.

The items were administered to subjects in individual sessions lasting between $1\frac{1}{2}$ and $2\frac{1}{2}$ hours. Adolescents were instructed to respond as they typically would in each problem situation; adults were asked to play the role of "expert advisors" and give what they considered to be the best response for a teenage boy to make in each situation. The examiner read each item aloud, the subject responded orally, and the response was recorded verbatim. In addition, any questions or difficulties were noted and used as guides in subsequent efforts to refine and clarify instructions and item wording.

Response evaluation. The purpose of this step was to evaluate the quality of the 23 responses per item obtained in the preceding step. Judges, working independently, were asked to rate the competence of these responses using whatever subjective criteria they felt were important. Thirteen adults (4 men, 9 women) volunteered to serve as judges; they were advanced undergraduate psychology majors, clinical psychology interns, and professional psychologists. Depending on the amount of time that they were able to volunteer, each judge rated between 22 and 90 items. For any particular item, the number of judges ranged from 8 to 13, with a median of 11. Each judge was given a 145-page packet containing the 90 items along with typed transcripts of 23 responses to each. Judges worked independently, at their own pace, at home. They were blind as to the purpose of the study and the origins of the responses that they were evaluating. To minimize possible order effects, the 23 responses to each item were arranged randomly; furthermore, 5 judges progressed from Item 1 to Item 90, 5 went from Item 90 to Item 1, and 3 worked from Item 45 outward in both directions.

All of the judges first classified each of the 23 responses to each item as "competent," "incompetent," or "neither competent nor incompetent."² Then they rated the *relative* competence of each of the 23 responses per item on a 50-point scale, ranging from 0 = *maximally incompetent* to 50 = *maximally competent*. In addition, four judges were asked to specify in writing, as explicitly as possible, which criteria they had used to

evaluate all of the responses to a particular item, and a fifth judge orally explained the criteria that he had developed. The 50-point ratings and the written criteria were used later in the construction of a rater's manual.

Based on judges' evaluations, the original list of 90 items was reduced to a final set of 44 items. Interjudge agreement and item difficulty were the two criteria used for item selection. An item was retained (a) if there was 75% or higher interjudge agreement in the competency classification of the 23 responses to it and (b) if 25% or more of the 23 responses to the item were judged to be incompetent by at least 75% of the judges.

Construction of the inventory and rater's manual. The 44 items meeting both criteria were rewritten and polished in a final effort to eliminate any ambiguities or other problems noted in preceding steps. These items, in their final form, comprised the API, which was designed to be administered as a behavioral role-playing test.

A rater's manual for the API was also developed in this step. The manual presented explicit criteria for rating subjects' responses to each of the 44 items on a 5-point scale. Scale values were 8, 6, 4, 2, and 0; these values corresponded to judgments ranging from very competent to very incompetent. The criteria, which were item specific, were based on data provided by judges in the preceding response evaluation step. The manual's criteria reflected the distinguishing characteristics of the responses that judges had identified as competent, incompetent, or neither. Finer distinctions among responses were made by taking into consideration judges' ratings on the 50-point scale. Whenever possible, the manual incorporated judges' statements concerning the criteria that they used in their evaluation of responses to particular items. Sample responses representing different levels of competency were also included in the manual.

² Judges were allowed to sort the responses without concern for their distribution across the three categories; for example, it was possible for a judge to classify all 23 responses to a particular item as "competent."

To illustrate the item format and scoring manual, one item (12) is presented in full below. In addition, Table 1 presents a summary abstract of all 44 problem situations retained in the final version of the API.³

It is 1:30 at night, and you're walking along a street near your home. You're on your way home from your friend's home, and you know it is after curfew in your town. You weren't doing anything wrong. You just lost track of time. You see a patrol car cruising along the street and you feel scared, because you know you can get into trouble for breaking curfew. Sure enough, the car stops next to you, the policeman gets out, and he says, "You there, put your hands on the car. Stand with your feet apart." What do you say or do now?

Score:

- 8—EITHER the subject does it without saying anything or he asks a brief general question respectfully.

EXAMPLE: "What's wrong, officer?" "Is something the matter?" or he explains honestly and convincingly where he was.

- 6—The subject explains where he was, etc., but in a less assertive or less convincing manner.

EXAMPLES "I just got out of Pete Jones' house. You can call him if you want to."

- 4—No specific criteria . . . midway between responses scored 6 and 2.

- 2—The subject is antagonistic or flippant or insolent.

- 0—EITHER the subject hits the policeman or he runs away.

Validation of the Adolescent Problems Inventory

In this phase of the research, the API was subjected to two tests of concurrent discriminant validity. The first was a study comparing the API responses of three groups of adolescent boys assumed to represent three points along a continuum of social competence: a group of institutionalized delinquents, a comparison group of nondelinquent peers ("good citizens"), and a group of nondelinquent adolescent "leaders." The second study involved a comparison between the API responses of two groups of institutionalized delinquents, who differed in terms of their frequency of their placement in a confinement cottage as a result of so-called acting-out behaviors, according to institutional records.

Study 1

Method

Subjects. There were three groups, with 20 Caucasian boys in each, for a total of 60 subjects.⁴ The three groups were as follows:

1. **Delinquents:** These boys were all residents of a state correctional institution for juvenile offenders. They ranged in age from 14.1 to 17.8 years ($M = 16.4$, $SD = .94$). According to Hollingshead's (Note 1) index of socioeconomic status, which is based on the head-of-household's educational level and occupation, the group's mean socioeconomic level was 50.9 ($SD = 10.52$); this indicates that the typical delinquent subject came from the working class (Class IV). The various offenses for which the boys had been institutionalized were car theft, sale and possession of drugs, burglary, robbery, battery, vandalism, truancy, runaway, forgery, and arson. It was the first stay in the state correctional institution for 14 of the boys, the second stay for 3, the third for 2, and the fourth for 1 ($M = 1.5$, $SD = .88$). The length of stay at the time of testing ranged from 3 days to 13 months.

2. **Good citizens:** These nondelinquent boys were attending a public school. They were selected by the school's guidance counselors, who were asked to nominate individuals who were law-abiding, mature, responsible, able to get along well with peers and adults, and involved either in extracurricular activities or after school jobs. Their ages ranged from 14.3 to 17.7 years ($M = 16.4$, $SD = .94$). The mean socioeconomic level for the group was 45.7 ($SD = 12.03$); like the delinquent subjects, they tended to come primarily from the working class. Prior to testing, each nondelinquent was asked whether he had ever experienced legal difficulties; no one admitted to having a police record.

3. **Leaders:** These subjects were also public high school students selected on the basis of guidance counselors' nominations. In addition to possessing all of the attributes of the good citizens, these subjects were recognized as student leaders; they were the editors of the school newspaper and yearbook, student senators, class presidents, and star athletes. Their ages ranged from 14.8 to 17.9 years ($M = 16.8$, $SD = .87$).

Preliminary analyses comparing the ages and socioeconomic levels of the three subject groups revealed only one significant difference: The mean socioeconomic status of the leaders ($M = 34.4$, $SD = 20.13$) was higher than that of the other two groups ($p <$

³ The Adolescent Problems Inventory was copyrighted by the first author and may not be used in any form without her written permission.

⁴ This initial study was limited to Caucasian boys due to the availability of subjects and to a concern about not examining too many variables in a single study. Obviously, the experimental results can be generalized only to Caucasian boys until subsequent research examines the relevance of the Adolescent Problems Inventory for non-Caucasian boys.

Table 1

Abstract of 44 Problem Situations Covered in the Final Version of the Adolescent Problems Inventory

1. A male, peer, stranger deliberately bumps into you on the street.^a
2. Same as #1, plus he blames you.^a
3. A gym teacher picks on you, makes you do extra pushups.^{a,b}
4. A friend suggests buying booze illegally.^a
5. Your father tells you to stay home on Saturday night.^a
6. You want to break up with your girlfriend without hurting her.^{a,b}
7. The school principal threatens to suspend you for hassling a substitute teacher.^a
8. You come home late at night and your father is waiting up for you and is angry.^{a,b}
9. Your are called names by some guy in the schoolyard.
10. Your mother tells you to put on decent clothes before leaving the house.^{a,b}
11. A friend wants you to deliver some drugs; he offers drugs and money in return.^a

^a Good citizens > delinquents.

^b Leaders > good citizens.

.005); the leaders tended to come from the upper middle class (Class II).

Procedure. The API was administered to subjects by a female examiner in individual sessions lasting approximately 1 hour each.⁵ After presenting the instructions, the examiner played an audiotape containing the 44 test items. For items involving interactions with men, the tape-recorded voice was that of a man; for interactions involving women, the voice was a woman's. The examiner presented the test items

one at a time, using a remote control switch to start and stop the stimulus tape. Subjects' oral responses were recorded on a second machine for subsequent evaluation by trained "blind" judges.

⁵ It is an unanswered empirical question as to whether the use of an adult female examiner had any significant effect on the teenagers' responses. Future research must examine this question.

Working independently, two raters listened to subjects' recorded test responses and rated the competence of each response on a scale ranging from 0 (very incompetent) to 8 (very competent), according to the criteria outlined in the raters' manual. Intermediate rating values (1, 3, 5, and 7) were permitted if judges felt that responses were midway between categories. The raters were a male and a female, both seniors majoring in psychology. The protocols of 10 subjects (5 delinquents, 5 nondelinquents) were used for training. Interrater reliability for the remaining 50 protocols was analyzed by computing the Pearson product-moment correlation between raters' scores for individual responses to all 44 items across all 50 protocols (i.e., the correlation was among 2,200 pairs of ratings). There was a high level of interrater agreement ($r = .99$). The mean of the two raters' judgments was used in all subsequent analyses.

In addition, data on IQ and grade point average for the preceding year were obtained on most subjects from institutional and school records. Unfortunately, the IQ estimates for nondelinquent and delinquent subjects were based on different tests: For nondelinquents the estimates came from the Henmon-Nelson test; for delinquents the estimates came from the Culture Fair Test, a nonverbal measure, and from the Wide-Range Vocabulary Test, a verbal measure.

Results

Across all 44 items, delinquents earned a mean score of 2.73 ($SD = .77$); the mean for good citizens was 5.86 ($SD = .65$); and the mean for the leaders was 6.77 ($SD = .60$). Planned group comparisons, based on total API score, revealed that the leaders performed significantly better overall than did the good citizens, $F(1, 57) = 19.63$, $p < .001$. An item-by-item comparison revealed that the leaders significantly outperformed the good citizens on 7 out of the 44 individual items.

Good citizens, in turn, performed significantly better overall than did the delinquents, $F(1, 57) = 217.71$, $p < .001$. This latter comparison is the one of greatest interest, since these two groups were comparable in mean age and socioeconomic level. An item-by-item comparison showed that the good citizens also performed significantly better ($p < .05$) than the delinquents on 42 out of the 44 individual items. In absolute terms, the delinquent group's deficient performance was reflected in their earned mean rating of less than 4.0 (i.e., a value more indicative of incompetence than competence)

on 36 of 44 items. In contrast, good citizens earned mean ratings of less than 4.0 on only 1 item. Leaders did even better, earning no mean ratings below 4.0 and a mean of 5.0 or better on all but one item.

Table 1, which provides a brief abstract of the 44 API situations, also indicates which items yielded significant group differences ($p < .05$) in the comparisons between leaders and good citizens and between good citizens and delinquents.

Grade point averages and IQ scores for the three groups were obtained from institutional and school records. The mean IQ scores of the two nondelinquent groups were not significantly different: leaders = 111.8 ($SD = 6.91$) and good citizens = 102.7 ($SD = 16.93$). However, leaders earned significantly higher grade point averages than good citizens: 3.25 ($SD = .50$) and 2.75 ($SD = .63$), respectively; $F(1, 35) = 5.20$, $p < .05$. The good citizen group, in turn, had a significantly higher mean IQ than the delinquent group, whose mean score on the Culture Fair Test was 93.2 ($SD = 10.13$) and on the Wide-Range Vocabulary Test was 87.4 ($SD = 10.09$); $F_s(1, 35) = 4.33$ and 11.12, respectively (both p s $< .05$). The delinquent group also had a significantly lower grade point average ($M = 1.80$, $SD = .93$), $F(1, 35) = 25.83$, $p < .05$. Overall, there was a strong correlation between total API scores and verbal IQ scores ($r = .70$, $p < .05$).⁶ When correlations were computed separately within the delinquent and the nondelinquent samples, however, the significant relationship disappeared (for delinquents, $r = .14$; for nondelinquents, $r = -.03$).

The troublesome relationship between IQ score and API performance could not be ruled out as a contributing factor in the obtained group differences on the API. Nor could the effect of IQ be satisfactorily controlled through statistical manipulations, such as analysis of covariance, because of the reasons cited by Lord (1967). Despite these

⁶ In this correlation, nondelinquent IQ scores were based on the Henman-Nelson test; delinquent scores were based on the Wide Range Vocabulary Test. When delinquents' IQs were estimated by the Culture Fair Test, the correlation was somewhat lower (.58).

limitations, the IQ data were examined in another way for heuristic purposes. Two subsamples of eight subjects each were drawn from among the most intelligent of the delinquents and the least intelligent of the nondelinquents; in this way, two subsamples equated on mean IQ were composed (delinquents' $IQ = 101.6$; nondelinquents' $IQ = 101.0$). The mean API scores of these groups (2.51 and 6.60, respectively) were still highly discrepant, $F(1, 14) = 85.00$, $p < .05$. Of course, these results are only suggestive, due to the problem of statistical regression and the fact that the selected subsamples may not have been representative of their parent groups. These results tend to imply that a subject's verbal skills may contribute to his scores on both the IQ and API measures, but the API seems to measure something above and beyond verbal intelligence.

Characteristics of the Inventory

Reliability. The API was designed to be an inventory, rather than a scale; nevertheless, a reliability analysis was performed using the entire sample of 60 subjects. The results of the analysis appear in Table 2. These statistics should be interpreted with caution, since they were computed on a sample containing only extreme groups rather than on a random sample of adolescent boys. The effect of using extreme groups is to inflate estimates of internal consistency such as the coefficient α and the corrected item-total correlation.

Item relationships. Because the number of situations relative to the number of subjects was large, it was not appropriate to perform a factor analysis with the present data. However, four hierarchical cluster-analytic techniques were used in an attempt to group situations on the basis of similarity of subjects' performance competence. A complete linkage and an average linkage cluster analysis were performed on both the correlation and the squared Euclidian distance matrices (Lance & Williams, 1967; Sneath & Sokal, 1973). The situational clusters that emerged differed from one technique to the other and were generally uninterpretable in terms of their content. Between 8 and 14

Table 2
Reliability Analysis of the Adolescent Problems Inventory

Variable	<i>M</i>	<i>SD</i>
Total score	225.48	9.06
Item <i>M</i>	5.12	.75
Item <i>SD</i>	2.86	.48
Interitem <i>r</i>	.39	.15
Corrected item-total <i>r</i>	.62	.13

Note. Coefficient alpha = .966.

weak clusters were identified, depending on the solution used. For example, one of the clusters in the complete linkage cluster analysis of the correlation matrix consisted of four situations: (a) "Your father forbids you to go out with a friend," (b) "you're embarrassed to ask a teacher for help," (c) "you're fired by your boss for accidentally being late to work," and (d) "a policeman comes to your door and asks for you." The majority of clusters showed a similar lack of interpretability. Even the two individual items with the strongest association ($r = .79$) were not related in a readily apparent way: #19. Your father gives you an ultimatum about getting your hair cut; #29. Your girlfriend offers you a joint at a party.

The lack of clear results in the cluster analyses indicates that competence scores are not the proper measure on which to construct a situational taxonomy. Instead, one probably would do better to classify situations either on the basis of the similarity among their stimulus properties or on the basis of the similarity of the specific behavioral task requirements of the situations. The lack of consistent clustering of the situations, in conjunction with their moderate intercorrelations, leads to the conclusion that competence scores show a rather high degree of situational specificity, especially when the items are specifically designed to be nonoverlapping in their content, as in the API.

Discriminating power. Although planned comparisons indicated that good citizens performed significantly better than delinquents on 42 of the 44 API items, the significant F s do not reveal the degree to which the API can actually discriminate between these groups. A discriminant analysis, which is

more appropriate, was performed using four sets of items from the API. Mean scores were computed for each of the 20 delinquents and 20 good citizens across 6 situations involving aggression (AGR), across 21 situations involving interactions with adult authorities (AUT), across 2 situations involving bad moods, (BM), and across 8 situations involving resistance to temptation (RTT). The resulting discriminant function was $Y = -.10AGR - .32AUT - .02BM - .14RTT + 2.53$. Probabilities of misclassification for this function were computed using the \bar{U} method of Lachenbruch and Mickey (1968), who showed that this method is superior to the method of validating the function by resubstituting the original data. The \bar{U} method gives good estimates of the results that would be obtained by using a fresh validation sample.

Results indicated that the estimated probability of misclassifying a delinquent is .00, and the estimated probability of misclassifying a good citizen is .11. In other words, the discriminant function based on the four content scores of the API was 89% correct when it was used to classify the subjects in the derivation sample. In particular, its success rate was 100% in correctly identifying the delinquents.

Since the proportion of delinquents in the derivation sample was .5, it would be misleading to use these results to estimate the performance of the API if it were applied to a more typical population of adolescent boys. Therefore, an additional analysis was performed using various base rates, selection ratios, and costs of misclassification, all of which are important factors that must be considered when evaluating the ability of an instrument such as the API to discriminate between delinquents and nondelinquents.

Considering the difficulties in correctly identifying a population with a very low base rate (Meehl & Rosen, 1955), the API can be expected to perform remarkably well. To illustrate, consider a hypothetical situation: Suppose there is a population in which the base rate of adjudicated delinquents is known to be .03, the selection ratio is fixed at .08, and it would cost 25 times as much to mis-

classify a delinquent as to misclassify a nondelinquent. Under these conditions, the results of our discriminant analysis indicate that the API could be expected to perform as follows if used to classify 100 boys: We could expect to be correct 95 times out of 100 in identifying delinquents and nondelinquents. This is superior to what we could expect if we were to try to identify boys on a random basis, in which case we would be expected to be correct only 90 times out of 100. A selection ratio of .08 means that we would be interested in selecting 8 out of every 100 boys (e.g., candidates for a training program). Applying our discriminant rule, 3 of these 8 would be delinquent (i.e., valid positives), and 5 would be nondelinquents. If we had elected instead to select 8 boys randomly, we could expect virtually no delinquents to be selected. Finally, the validity coefficient of the API, in this context, is .60, which is the mathematically derived, theoretical upper limit to the validity that *any* instrument could attain.

Study 2

Subjects in the preceding validation study were presumed to represent three levels of performance along the full continuum of social competence. The purpose of this second validation study was to determine how well the API could differentiate between two groups of boys representing less extreme points on that continuum. Specifically, the study compared the API performances of two groups of institutionalized delinquent boys who were known to differ in their history of disruptive behaviors and rule violations within the institution.

Method

There were two groups, with 15 Caucasian delinquent boys in each, for a total of 30 subjects. All were residents of a state correctional facility at the time, and none had been subjects in the first study. One group was comprised of boys whose records indicated that they had a history of frequently engaging in disruptive behaviors within the institution; that is, they had spent more than 25 days ($M = 50.13$ days) during the preceding 6 months in the institution's security cottage as a result of running away, possessing drugs or contraband, assaulting peers or staff, or other serious misbehaviors. The second group

was comprised of boys who had spent less than 5 days ($M = 1.74$ days) in the security cottage during the same period.

The boys ranged in age from 14 to 17 years. The mean age of the high-disruptive group was 16.46 years ($SD = 2.82$); for the low-disruptive group, it was 16.40 ($SD = .75$). A comparison of the mean socioeconomic backgrounds of the two groups was not statistically significant; however, the high-disruptive boys tended to come from Class V families, whereas the low-disruptive boys tended to come from Class IV families. The testing procedure was identical to the one used in the first study. The two raters in the present study achieved absolute agreement on 93.5% of their ratings for individual responses to each of the 44 items by each of the 30 subjects.

Results

A one-way analysis of variance revealed that the low-disruptive subjects earned significantly higher total scores on the API than did high-disruptive subjects, $F(1, 28) = 5.92$, $p < .025$. Furthermore, in an item-by-item comparison, the low-disruptive group performed better on 32 of the 44 items, $\chi^2(1) = 8.64$, $p < .01$.

Study 3

This study addressed two important and unanswered questions from the previous studies. First, it assessed whether poor API performance is actually due to skill deficits, as hypothesized, or whether it is simply an artifact of the task's instructions. Standard API instructions are "Imagine that you're actually in the situation, and tell me in your exact words what you would say or what you would do if you were really there." Presumably, the delinquent subjects faithfully followed the instructions and reported their typical responses. It is possible that they would have given more competent responses, however, if they had been asked to give the *best* responses that they could think of, rather than their *typical* responses. This possibility was explored in this study.

Second, assuming that delinquents do have skill deficits, what is the specific nature of such deficits? In previous studies, the API was administered in an open-ended, free-response format. The present study examined whether delinquents would show comparable deficits if the API were administered in a

multiple-choice format. Delinquents may be deficient at *generating* competent responses, but would they also be deficient at *recognizing* competent responses?

The present study also introduced two methodological refinements to the basic paradigm used in the preceding studies. The first dealt with subject selection. In Study 1, good citizens were selected on the basis of guidance counselor nominations. Post hoc analyses indicated that the good citizens and delinquents were comparable on mean age and socioeconomic status but not on IQ. In the present study, each delinquent subject was carefully prematched on age, socioeconomic status, and IQ with a nondelinquent subject, who was drawn from public school files.

The second refinement was in the area of response ratings. In Studies 1 and 2, raters listened to the audiotaped responses of each subject to all 44 API items before proceeding to rate the next subject's responses. This procedure may have introduced a rating bias. For example, a subject's early responses may have contaminated ratings of his later responses. A subject's grammar, diction, or revelation of illegal behavior may have led a rater to give that subject a generally negative evaluation. To control such influences in the present study, typed transcripts of subjects' responses were rated. Furthermore, raters evaluated all subjects' responses to a given item before proceeding to the next item; the order of answers within each item was randomized.

Method

Subjects. The subjects were 40 delinquent boys from the Wisconsin School for Boys at Wales and 40 nondelinquent boys from the Madison Public School System. All were Caucasian, 16 or 17 years old, with IQs between 82 and 117. All were from families in which the head of the household was a small independent business person; clerical or sales worker; or skilled manual, semiskilled, or unskilled worker. Public school boys were asked if they had ever been in any trouble with the police; only those who indicated that they had not were included in the study.

Each delinquent subject was matched with a nondelinquent youngster of approximately the same age, IQ, and socioeconomic status. Of necessity, available scores were used to estimate subjects' IQs. Unfortunately, the intelligence tests previously administered to the two populations were not the same; the Wide-

Range Vocabulary Test was used for the delinquents, and the Lorge-Thorndike Intelligence Test was used for the nondelinquents. Socioeconomic status was estimated using the Occupational scale of the *Two-Factor Index of Social Position* (Hollingshead, Note 1).

Design. A $2 \times 2 \times 2 \times 2$ factorial design was used. The four factors were subjects (delinquent vs. nondelinquent); instructions (standard—"What would you do" vs. alternate—"What is best to do"); test format order (free-response format administered first vs. multiple-choice first); and item-group order. (The half of the items administered first to one group of subjects was administered second to the other group of subjects, and vice versa.) These four factors yielded 16 experimental cells, with five subjects per cell. Matched pairs of delinquent and nondelinquent subjects were randomly assigned to cells across the remaining three factors.

Each subject was administered all 44 API items under only one set of instructions—either standard or alternate. However, every subject was administered one half of the test in a free-response format and the other half in a multiple-choice format, with the format order balanced across subjects. To control for possible differences due to item content, the 44 API items were split into two equivalent groups of 22 items each. The presentation order of item groups (A and B) was balanced across subjects, instructions, and test formats.

Development of stimuli. The alternate instructions for the API told the subject to describe "What you think someone should say or do in that situation—not necessarily what you would do, but what you think is the best way someone could solve that problem?"

The multiple-choice version of the API was constructed by writing five response alternatives for each of the 44 items. The five options per item were derived from the response criteria given in the API scoring manual. The five responses corresponded to the points on the manual's 5-point rating scale: very competent, competent, neither competent nor incompetent, incompetent, and very incompetent.

Item Groups A and B, with 22 items each, were constructed as follows: All API items were classified according to the type of interaction involved (e.g., with parents, teachers, male peers, girls, police, etc.). The items from each category were divided as equally as possible between Item Groups A and B. The equivalency of the resulting groups was then checked by examining the scores on A and B items previously earned by subjects in Study 1: delinquents: $t(42) = .408$; good citizens: $t(42) = .973$; and leaders: $t(42) = .198$ (all *ns*). The item groups appeared to be satisfactorily equivalent.

Procedure. The procedure was identical to that in Study 1, except for the following important modifications or additions:

Each subject was individually administered one of the eight possible versions of the API by a female experimenter. To control for differences in reading ability, the subject listened to an audiotaped presentation of the API at the same time that he read from

the written test. If multiple-choice items were being presented, the five alternative responses also were presented on the audiotape, as well as in the written test.

During the free-response half of the test, the subject responded orally to each item, and his response was tape-recorded for subsequent transcription and scoring by raters. In the multiple-choice half of the test, the subject responded to each item by circling the letter corresponding to his response choice on the test booklet. The experimenter subsequently scored the multiple-choice responses with a key, assigning values on a 5-point scale (0, 2, 4, 6, and 8), corresponding to the competence criteria in the original API scoring manual.

Typed transcripts were made of subjects' oral responses under the free-response format. These transcripts then were edited to remove conspicuous use of grammar, word choices, or self-disclosure that might inadvertently reveal the identities of delinquent subjects. Finally, these typed responses were grouped by item and randomized for subsequent rating by four volunteers from an advanced undergraduate psychology class. One pair of raters rated half of the items; the other pair rated the rest. Across all items in Group A, the mean interrater agreement was .81, with the intercorrelations on individual items ranging from .64 to .93. Across all items in Group B, the mean agreement was .74, with interrater agreement on individual items ranging from .49 to .94. When raters were asked to repeat their ratings of selected items, as a way of estimating intrarater reliability, the mean was .90, with a range between .76 and .96.

Results

To evaluate whether the subject selection procedures yielded equivalent groups, t tests were performed on the delinquent and nondelinquent groups for the three matching variables of age, IQ, and socioeconomic status. There were no significant differences on age, $t(39) = .545$, or socioeconomic status, $t(39) = .206$. There was, however, a significant difference on IQ scores, $t(39) = 2.967$, $p < .05$, with nondelinquents scoring higher. Although the IQ difference between groups was statistically significant, the absolute magnitude of the difference was too small to be very meaningful. One standard deviation on the intelligence tests that were used is 15 points; yet, the mean IQ difference between delinquent subjects and their matched controls was only 3.8 points, with a range between 0 and 13 points. Moreover, a Pearson product-moment correlation computed across all subjects between IQ and total API scores

Table 3

Mean Response Ratings and Standard Deviations for Subjects in Each Testing Condition

Group	Test A		Test B		Test A		Test B

Note. 1 and 2 refer to items taken first and second, respectively.

was nonsignificant and relatively low (.06). This suggests that there was a negligible relationship between IQ scores and performance on the API.

Results were analyzed by two separate analyses of variance, one for free-response items and one for multiple-choice items; since it could not be assumed a priori that free-response and multiple-choice formats were equivalent, it was not appropriate to treat them as repeated measures within a single overall analysis of variance. Table 3 presents the mean response ratings and standard deviations for the subjects in each testing condition. The group means, collapsed across format order and item-group order, are graphically presented in Figure 1.

There was a significant performance difference between delinquents and nondelinquents both on the free-response version of the API, $F(1, 64) = 21.68$, $p < .001$, and on the multiple-choice version, $F(1, 64) = 10.59$; $p < .005$. Delinquents earned a mean rating of 4.13 on free-response items ($SD = 1.33$), and nondelinquents earned a mean of 5.19 ($SD = .76$). On the multiple-choice version, delinquent subjects had a mean score of 5.25 per item ($SD = 1.48$); for nondelinquents, the mean was 6.06 ($SD = .65$).

Within the free-response format, there was a significant main effect due to instructions, $F(1, 64) = 5.30$, $p < .05$, with the alternate instructions (which called for subjects to give the *best* response) leading to higher scores than the standard instructions (which asked subjects to tell how they would actually react in the various situations). This same instruction effect was not present in the multiple-choice version of the API, $F(1, 64) = 3.42$.

The performances of delinquents and nondelinquents also were compared under standard versus alternate instructions within each of the test formats (i.e., free response and multiple choice). The Kolmogorov-Smirnov two-sample test was used for these comparisons; it assesses the similarity of the distributions of scores for the two subject groups. Significant differences were found between delinquents and nondelinquents in the free-response format with both standard instructions ($p < .01$) and alternate instructions ($p < .05$). In the multiple-choice format, however, no significant differences were found for either set of instructions.

To compare within-group performance on the multiple-choice and free-response formats, matched t tests were performed. Delinquents

Figure 1. Mean response competence of delinquents and nondelinquents under two sets of instructions (standard vs. alternate) and two test formats (free response vs. multiple choice).

performed significantly better on the multiple-choice version than on the free-response version, $t(39) = 8.86$, $p < .001$. The same pattern was also found with nondelinquents, $t(39) = 3.55$, $p < .001$.

Significant differences were found between delinquents and good citizens on 42 out of 44 items in Study 1. In the present study, however, an item-by-item comparison between mean scores obtained under standard instructions in the free-response format (i.e., the instructions and format used in Study 1) yielded significant group differences ($p < .05$) on only 13 items. This result must be qualified by a number of considerations: The present study was designed with different objectives in mind; the number of subjects contributing to the group mean on each item was only 10, 5 of whom were administered the free-response test following the multiple-choice test; and there was a tendency for subjects to perform better on free-response items after being exposed to the multiple-choice items and answers. Furthermore, re-

sponses in this study were rated from typed transcripts rather than from audiotapes, and this may have eliminated some of the distinguishing response behaviors. It was deemed inappropriate to attempt a more detailed item analysis with the present data, since there were only 5 subjects per cell.

Discussion

The first phase of this research was concerned with the development of a behavioral role-playing inventory of social skills in adolescent boys—the API—and a criterion-referenced raters' manual to accompany the inventory. The second phase was concerned with evaluating the API. Three studies were conducted, along with several psychometric analyses of the inventory itself.

Study 1 found that the API could differentiate between delinquents and nondelinquents, and that nondelinquents who differed in their social competence, according to school guidance counselors' nominations, also differed in

their overall API performance. The API was shown to be reliable; to lack any strong, coherent, or interpretable item structure; and to be an unusually strong predictor of subjects' group membership. Study 2 demonstrated that the API was not merely sensitive to gross differences between delinquent and nondelinquent groups. Institutionalized delinquents who were known to differ in their disruptiveness within the institution also were significantly different in their API performance. This finding suggests that subcultural differences alone probably do not account for differences in API performance.

The third study replicated the previous findings. The API again differentiated between delinquent and nondelinquent subjects. Such differences were found even though several methodological improvements were introduced—namely, in subject-matching and in response-rating procedures. Moreover, the study found that instructions affected the API performances of both delinquents and nondelinquents: When told to respond with "the best" solution, all subjects did better than when they were told to say what they would actually "do." The study also showed that all subjects did better when given the API items in a multiple-choice format than when given the items in a free-response format.

Taken as a whole, the present research attests to the utility of a competence model of assessment. Specifically, the research suggests that the API is a valid measure of social competence in adolescent boys. Generally, the research provides support for the hypothesized relationship between social skill deficits and interpersonal/legal difficulties.

The findings of the present research are consistent with the results of previous studies in the area of delinquency. Numerous investigators have repeatedly demonstrated that delinquents, as a group, do not perform as satisfactorily as nondelinquents on a variety of measures. The critical difference between this research and previous work is not in its demonstration of performance deficiencies among delinquents; rather, the difference is in how it proposes that such deficiencies should be identified, assessed, and interpreted. Previous investigators typically have sought

to isolate either a core cause (e.g., genetic flaw; weak superego) or a unitary personality trait (e.g., aggressiveness) to explain delinquency. The present research, in contrast, was based on the notion that a wide and varied array of skill deficits may be related to delinquent behavior. Both delinquents and nondelinquents are likely to perform competently in some tasks and incompetently in others, and the pattern of particular deficiencies will vary considerably among individuals and within groups. No single deficit or pattern of deficits is likely to explain delinquency. Rather, the probability that an individual will be classified as a delinquent increases as a function of at least three factors: First, it increases to the extent that the individual lacks the requisite skills to deal effectively with the everyday problem situations confronting him; second, it increases as a function of the frequency with which he encounters such problem situations; and third, it increases as a function of the degree to which his incompetent solutions to such problem situations take the form of illegal behaviors.

Although the present research is a first step toward identifying some of the relevant problem situations and common performance deficits characteristic of delinquent boys, a number of important questions remain to be answered by future research.

First, it will be important to gather additional evidence on the external validity of the API; that is, do subjects' role-played responses to the API correlate with their actual responses to the same situations in real life?

Second, far more attention must be devoted to the task of defining situation-specific response competence before we can feel confident about using the API situations and scoring criteria to develop a valid skill-training program for adolescent boys. The criteria for evaluating competence in the present research were based on the judgments of so-called experts. Even though it is encouraging that there was consensus among the judges and that their criteria successfully discriminated among subject groups, it is possible that such criteria simply are not valid when applied to the life contexts of delinquents. A

response that is an effective solution to an interpersonal problem in one milieu may not be very effective in another. Rather than relying on the subjective opinions of judges to define competence, future research should take a more empirical approach; competence in a specific situation should be defined in terms of an objective assessment of the actual consequences of the various response alternatives.

The competence model and the methodology of the present study might profitably be applied to the assessment of other pathological behaviors (e.g., depressive behaviors, alcohol abuse). Gradually, a classification could be developed of particular problem situations and skill deficits that are associated with a variety of clinical populations. Such a classification could be individualized to take into account the specific strengths and weaknesses in the skills repertoire of any new client. Since treatment programs are only as good as the underlying assessment, those of us involved in social skills training might do well to call a moratorium on the further elaboration of treatment programs until we have more systematically assessed both the nature of the clinical problem and the type and extent of the skill deficits of the individuals with whom we are working.

Psychosocial Correlates of Empirical Types of Multiple Drug Abusers

G. Nicholas Braucht

G. James Berry

Systems Evaluation and Research Corporation, Denver, Colorado

The present study had three primary focuses: (a) to identify major empirical clusters of multiple drugs; (b) based on these empirical drug clusters, to develop an empirical typology of multiple drug abusers; and (c) to characterize each derived drug cluster and type of multiple drug user in terms of a coherent set of theoretically based psychosocial variables. To accomplish these objectives, drug use and psychosocial data were collected from 440 clients in four drug and alcohol treatment programs. A cluster analysis was performed on chronicity/frequency indices that had been calculated for each of 15 drug classes. Four multiple drug clusters were identified by this analysis: (a) cocaine/other opiates and synthetics/methaqualone/illegal methadone; (b) inhalants/codeine/nonnarcotic analgesics; (c) marijuana/amphetamines/hallucinogens; and (d) minor tranquilizers/barbiturates. Two substances, heroin and alcohol, did not cluster with any other substances but were frequently used by this sample, and consequently these two substances were retained in further analyses, yielding six basic drug clusters. Next, a typology of drug abusers, rather than drug clusters, was developed empirically by means of proximity cluster analysis. Eight quantitatively and qualitatively distinct types of multiple drug abusers were identified solely by analysis of their standing on the use of the six basic clusters of drugs. Finally, the set of psychosocial measures was found to be differentially related to use of the six types of drugs and to the eight types of drug abusers. These differential findings were discussed in terms of the adequacy of the theory underlying the measures and in terms of alternative analytic strategies.

Evidence has accumulated in recent years documenting a substantial increase in the polydrug and multiple drug abuse patterns encountered in a variety of drug treatment settings (Benvenuto & Bourne, 1975; Carlin

& Post, 1971; Duncan, 1975; Fisher & Brickman, 1974; Smith & Wesson, 1973), involving a concomitant proliferation of distinctive multiple drug use patterns, that is, regular use of two or more kinds of drugs. Consequently, there is a pressing need for systematic research into identification of the major types of multiple drug abusers requiring some kind of drug treatment. To develop such a typology, an initial task is to identify major patterns of multiple drug abuse and to describe the psychosocial factors that are associated with each major pattern. The present study has three primary aims: (a) to identify major empirical clusters of multiple drugs; (b) based on these empirical clusters, to develop an empirical typology of

This study was supported in part by funds provided by the Special Action Office for Drug Abuse Prevention and the National Institute of Drug Abuse through the Colorado Department of Health and the Denver Department of Health and Hospitals (Grant 1-H81-DA-01687).

The authors wish to express their gratitude to both agencies and the staffs of the treatment centers involved in the study.

multiple drug users; and (c) to describe each cluster of drugs and type of user in terms of the same set of theoretically derived psychosocial variables.

From a review of the existing research literature in this area, it is our contention that the simultaneous investigation of these three aims would represent a distinct advance over present research strategies. This is so because nearly all of the present literature germane to the above aims reflects one of four approaches:

1. Some investigators have attempted to identify distinct patterns of multiple drug abuse but have provided no information about the distinguishing characteristics of persons using different patterns of drugs (e.g., Simpson & Sells, 1974; Smart & Whitehead, 1972).

2. Others have provided systematic descriptions in terms of theoretically articulated sets of psychosocial variables and their relationships to various forms of social deviance, but these investigators have not focused on patterns of multiple drug use nor have they studied significant numbers of drug abusers with problems of the magnitude typically encountered in drug treatment populations (e.g., Braucht, 1974; R. Jessor, 1976; R. Jessor, Jessor, & Finney, 1973).

3. A third approach is represented by studies concerned with only one pattern of multiple drug abuse, often providing anecdotal or demographic descriptors not based on any identifiable theoretical perspective (e.g., Campbell & Freeland, 1974; Chambers, 1969; Devenyi & Wilson, 1971; Hamburger, 1964; Kirby & Berry, 1975; Ludwig & Levine, 1965).

4. A fourth approach has attempted to identify multiple drug use patterns among general high school or college populations (e.g., Blum, 1969; Brehm & Back, 1968; Groves, 1974; Johnston, 1973) or has attempted to describe initial stages in the progression of drug use among general adolescent populations (Kandel, 1975; Kandel & Faust, 1975; Single, Kandel, & Faust, 1974)—populations without significant numbers of persons having the extensive involvement, experience, and advanced problems with drugs

that constitute the norm among drug treatment clientele.

Against this background of extant research strategies and knowledge, it would be advantageous to develop research that would integrate the best features of these lines of inquiry. Thus, the focuses of the present article are on the identification of distinct types of multiple drug use patterns and multiple drug users in a large sample of persons having major drug problems and on an analysis of the psychosocial characteristics of those types of multiple drug users.

Having stated the objectives and *raison d'être* for the present study, the literature would suggest that an optimal investigation of these objectives must possess several key methodological features. To achieve the first two objectives—identifying major empirical clusters of drugs and types of multiple drug abusers—three requirements must be met: (a) the reduction of a large potential number of drug use patterns to some manageable number without loss of information, a requirement met by any of several forms of dimensional analysis; (b) obtaining a large, maximally heterogeneous sample of persons who are regular users of more than one kind of drug; and (c) assessment of the frequency and chronicity of each kind of drug used for each person in the sample.

To address the third objective—theoretically based differential descriptions of multiple drug use patterns and types of multiple drug abusers—an approach that appears to be promising in accounting for drug abuse must be identified, and appropriate measures derived from the theory must be selected. In the present study, the theoretical approach is a variant of social learning theory as developed by Jessor and his colleagues (R. Jessor, Graves, Hanson, & Jessor, 1968; R. Jessor & Jessor, 1977). This theory has been fruitful in understanding and predicting adolescent deviant behavior, including alcohol and marijuana use. Principal measures in this study included a set of sociocultural and personality variables developed by R. Jessor et al. (1968), R. Jessor, Collins, and Jessor (1972), R. Jessor et al. (1973), R. Jessor (1976), R. Jessor and Jessor (1975), and Braucht (1974). It should be emphasized that the

present study is not intended to be a theory-testing endeavor; rather, as an initial exploratory inquiry, the present study uses these theory-based variables in a purely descriptive role.

Method

Structured interviews were conducted, with 440 clients receiving treatment in seven drug programs located in the Denver metropolitan area. The largest percentage were patients in the Polydrug Treatment Center ($n = 164$); 100 were patients in the Denver General Hospital Alcohol Detoxification Ward; 102 were patients in two methadone programs; and the remaining 74 were patients in three other Denver drug programs. The anonymity of respondents was assured. Across this sample of 440 clients, the average age was 30.5 years, 73% were male, and the ethnic groups represented were as follows: 48% Anglo American, 31% Mexican American; 14% Black-American, and 7% American Indian or Oriental. The socioeconomic level of the sample was predominantly lower middle class. It may give some perspective on the nature of this sample to note that 59% reported having been convicted of at least one (nontraffic-related) crime, whereas 44% reported two or more convictions.

Data collected included age, sex, ethnicity, socioeconomic status level, number of arrests, and number of convictions (lifetime basis, whether drug related or not); a two-factor self-concept scale (Miskimins & Braucht, 1971); a scale of stressful life events (Holmes & Rahe, 1967); a measure of assaultiveness (Buss & Durkee, 1957), and a measure of hostility guilt (Mosher, 1966). The interview also included 34 other psychosocial scales; because these measures and the theoretical framework from which they were derived have been described previously (Braucht, 1974; R. Jessor et al., 1972; R. Jessor et al., 1968; R. Jessor & Jessor, 1975; S. L. Jessor & Jessor, 1974), they will not be elaborated on here.

Many investigators, including Sadava (1975), Walizer (1975), and Gorsuch and Butler (1976), have noted that most studies of drug use have limited value because they have relied either on simple measures of use versus nonuse of a particular drug or have measured drug use along a set of absolute frequency of use categories, ignoring both (a) the length of the period of time during which the drug had been used and (b) the total pattern of multiple polydrug use. The present approach attempted to redress both of these limitations by assessing the use of a number of drugs in terms of both the frequency of use and the length of time that these drug(s) had been used.

Fifteen drug classes were studied: heroin, illegal methadone, other opiates and synthetics, alcohol, barbiturates, amphetamines, cocaine, marijuana, hallucinogens, codeine, nonnarcotic analgesics, volatile inhalants, major tranquilizers, minor tranquilizers, and methaqualone. Each client was questioned extensively as to current and past drug use history for each of the 15 drug classes.

During pilot work with clients of three of the drug programs, it was found that they could reliably provide information about which drugs they had been using on a recent, regular basis, and that they could also reliably report how frequently they used these drugs and how long they had been using them. To incorporate as much of this information as possible in a single index for each of the 15 drugs, a chronicity/frequency (C/F) index was calculated for each drug class used, representing the product of (a) the number of months of recent, regular use of that drug and (b) the number of times per week that the person used the drug across the time in a above. Thus, for example, a drug used either for 6 months on a daily basis (6×7) or for 3 months on a twice daily basis (3×14) yields a C/F index of 42; a drug used daily for 1 year yields a C/F index (12×7) of 84; and a drug used three times per day across a period of 1 year (12×21) yields a C/F index of 252. It should be noted that except for alcohol use, the definition of "regular use" was left to the subject. That is, the interviewer did not attempt to impose a predetermined definition for the amount of a drug that constituted a single use of the substance. With regard to alcohol use, the questions asked specifically about drinking to drunkenness, so that drinking to a drunken state constituted a single use episode for this drug.

Results

Cluster Analysis of Chronicity/Frequency Indices

To identify the most general groups of drugs defined by the 15 C/F drug use indices, a full cycle key cluster analysis was performed (Tryon & Bailey, 1970). Four cluster dimensions were identified involving 11 of the original 15 drugs. The remaining four drugs included (a) heroin, (b) alcohol, (c) major tranquilizers, and (d) the over-the-counter drugs.

Inspection of the mean C/F indices across the entire sample for the latter four drugs showed that the major tranquilizers and over-the-counter drugs were little used (12th and 14th ranked of the 15 drugs), whereas heroin (6th ranked) and alcohol (2nd ranked) were used to a considerable degree. For this reason, both heroin and alcohol were included as the 5th and 6th basic drug clusters in addition to the four identified by the empirical key cluster analysis. Even though these two single substances are not clusters of multiple drugs, it was decided to retain them throughout subsequent analyses in order to provide a com-

parative perspective against which the four true clusters could be viewed.

The resulting six drug substance dimensions (patterns of multiple drug use involving 14 of the original 15 drugs) accounted for 99% of the original communality and 92% of the mean square of the original correlation matrix. Thus, these six clusters of drugs can be studied as they relate to each other and to other variables with very little loss of information. In the section below, each cluster is described in terms of (a) the drugs defining the cluster and (b) statistics indicating the strength of association among usage of the drugs defining each cluster.

Drug Cluster 1: (*cocaine, other opiates and synthetics, methaqualone, and illegal methadone*). The use of the four drug classes comprising this basic drug cluster is highly interrelated—The heavy user of one drug class is very likely to be a heavy user of the other drugs and vice versa. This is evidenced by the domain validity for this first drug cluster of .85 and the cluster score's alpha reliability coefficient of .72. Across the entire sample the average intercorrelation of the C/F drug use scores among these four drugs was .40.

Drug Cluster 2: (*inhalants, codeine, and nonnarcotic analgesics*). The use of inhalants, codeine, and the nonnarcotic analgesics is also strongly related in our sample—Persons who use one heavily are likely to be heavy users of the other two. This drug cluster had a domain validity of .82 and an alpha reliability of .68. Across the entire sample, the average intercorrelation of these three C/F drug use scores was .36.

Drug Cluster 3: (*marijuana, amphetamines, and hallucinogens*). As shown by this third cluster's domain validity (.76) and the cluster score's alpha reliability (.57), the degrees of use of marijuana, amphetamines, and hallucinogens are strongly associated with one another—The heavy user of one is likely to be a heavy user of the others. Across the sample as a whole, the average intercorrelation of the C/F drug use scores for these three drugs was .28.

Drug Cluster 4: (*minor tranquilizers and barbiturates*). The use of minor tranquilizers and barbiturates was significantly as-

sociated in our sample ($r = .36, p < .001$). This drug cluster's domain validity was .62, and its alpha reliability was .38. Thus, the heavy user of barbiturates is also likely to be a heavy user of the minor tranquilizers and vice versa.

As stated earlier, neither heroin nor alcohol formed a multiple drug pattern with one another or with any other drugs. Because of the significant levels of use of both heroin and alcohol in this sample, however, these two drugs have been included as the fifth and sixth basic drugs in the remaining analyses.

Correlations Among the Six Clusters of Drugs

The correlations among the cluster scores for the six patterns of multiple drugs are presented in Table 1, which shows that the six clusters form moderately intercorrelated oblique clusters of multiple drugs.

Relationships Among Use of the Six Basic Patterns of Drugs and Other Drug Use Variables

Table 2 presents correlations among the six basic drug cluster scores and scores on four indices of polydrug use: (a) number of drugs (up to 15 possible) ever used; (b) number of drugs used recently on a regular basis; (c) number of drugs used recently on a daily basis; and (d) extent to which subjects reported the deliberate use of drugs in combinations for the express purpose of achieving some desired effect.

It may give some perspective on the relationships in Table 2 to note that across the entire sample, the mean number of drugs ever used was 6.5 drugs (out of a possible 15), that the average number of different drugs currently used on a regular basis was 2.8 drugs, and that an average of 2.0 different drugs were being used on a daily basis.

Relationships Among Use of the Six Types of Drugs and Psychosocial Variables

Table 3 presents the correlations among use of the six clusters of drug use (based on simple sum, nominally weighted cluster scores) and selected psychosocial variables.

Table 1

Intercorrelations, Internal Consistency, and Mean Use Levels of the Six Empirical Clusters of Drugs

Drug cluster	1	2	3	4	5	6
1. Cocaine/other opiates & synthetics/ methaqualone/illegal methadone	—	.06	.24**	.12*	.10*	.05
2. Inhalants/codeine/nonnarcotic analgesics		—	.15**	.24	-.04	.00
3. Marijuana/amphetamines/hallucinogens			—	.11*	.19**	.05
4. Minor tranquilizers/barbiturates				—	-.03	.07
5. Heroin					—	-.06
6. Alcohol (to drunkenness)						—
Domain validity of drug type cluster	.85	.82	.76	.62	—	—
Alpha reliability of drug type cluster score	.72	.68	.57	.38	—	—
<i>M</i> chronicity/frequency of use	68.8	27.6	293.0	94.8	45.6	118.8

* $p < .05$.

** $p < .01$.

Table 3 shows that the six drug cluster scores are differentially associated with 36 psychosocial variables (7 other variables that were available for this analysis do not appear in Table 3 because correlations with them failed to reach the $p < .01$ level).

First, Table 3 shows that the level of use of the first drug cluster (cocaine/other opiates and synthetics/methaqualone/illegal methadone) is significantly related to only two psychosocial variables. A high level of use of drugs in this first cluster is associated with (a) the presence of a peer subculture that is supportive of such drug use and (b) a high level of life stresses (the only group of multiple drugs to be significantly related to life stress level).

Second, Table 3 shows that the use of

the inhalants/codeine/nonnarcotic analgesics cluster is significantly related to six psychosocial variables. The greater the use of drugs belonging to this second cluster, (a) the less the religiosity, (b) the greater the alienation, (c) the more external the locus of control orientation, (d) the more important the personal effects (escape from problems) functions of such use, (e) the more strained the communication regarding drugs with one's family, and (f) the greater the discrepancy between the kind of person one feels one is versus the kind of person one would ideally like to be. A group picture suggested by this array of relationships is that inhalants/codeine/nonnarcotic analgesics use is associated with a psychosocial syndrome of alienation, lack of values and norms, lack of meaning-

Table 2

Significant Correlations Among the Six Empirical Clusters of Drugs and Four Indices of Polydrug Use

Polydrug index	Cluster					
	1	2	3	4	5	6
No. drugs ever used		.16	.40		.16	-.20
No. drugs used recently on a regular basis	.37	.27	.66	.23	.15	
No. drugs used recently on a daily basis	.96		.13			
Extent of the use of drugs in combination to achieve an effect	-.14	.17	.60	.30		

Note. All table entries are correlations significant at the $p < .01$ level; correlations that failed to attain significance at the $p < .01$ level have been omitted.

ful channels of communication with one's family, feelings of helplessness and inferiority, and a strong desire to escape from the pressure of personal problems.

Inspection of Table 3 shows that the use of the third class of drugs (marijuana/amphetamines/hallucinogens) is related to 25 psychosocial characteristics (presented in the third column of Table 3). The general psychosocial condition suggested by this array of significant relationships is one of marijuana/amphetamines/hallucinogens use on the part of youth embedded in family and peer groups

who model and support drug use. The use of drugs in this cluster appears to be firmly entrenched in a drug subculture with all of its characteristics as popularly conceived. Use of this cluster is not only associated with the desire to escape from personal problems but is also associated with the function of enhancing social occasions, the only class of drugs that is perceived to serve this social enhancement function.

In contrast, Table 3 shows that use of the minor tranquilizers/barbiturates cluster is associated with a pattern of psychosocial char-

Table 4
Drug Use Cluster Score Profiles of the Eight Types of Drug Users

Type	n	%	Profile						Overall homogeneity
			1	2	3	4	5	6	
1. Infrequent experimenters	230	55.0	48.0	48.5	45.8	47.1	48.1	45.3	.99
2. Alcoholics	67	16.0	47.9	48.7	46.9	47.2	47.5	71.0	.96
3. Minor tranquilizer/barbiturate users	17	4.1	49.9	49.0	47.3	80.0	47.5	46.7	.90
4. Heavy heroin and some cocaine/other opiates (no illegal methadone users)	16	3.8	50.9	48.4	50.3	47.5	101.2	45.2	.91
5. Hallucinogen and minor tranquilizer barbiturate users	11	2.6	48.0	48.8	60.4	60.9	47.8	46.6	.86
6. Heavy minor tranquilizer/barbiturate and some codeine/inhalant/analgesics users	8	1.9	50.0	54.0	45.2	58.6	48.4	46.6	.93
7. Codeine (heavy), inhalant/analgesics and some minor tranquilizer/barbiturate users	7	1.7	49.6	77.0	45.4	52.5	47.5	44.7	.89
8. Hallucinogen users	62	14.9	48.5	48.6	61.2	47.3	48.8	45.6	.92
Eta			.98	.98	.91	.98	.97	.97	

acteristics suggestive of older users who are intolerant regarding deviance from conformist ethos, who have pervasive feelings of helplessness in controlling their own destiny, and who lack confidence in their own vocational career success.

The use of heroin is related to only two psychosocial variables: Heavy heroin use is associated with having been arrested several times and with a family ethos that places a high value on the importance of conformist goals.

Finally, Table 3 shows that the use of the last basic type of drug (alcohol) is related to older user age, importance attached to using alcohol as a means of conforming to social expectations, elevated levels of criminal arrests and convictions, low socioeconomic status, and a classic sign of depression—the feeling that others think more of one than one thinks of oneself.

Identifying Distinct Types of Drug Abusers

Thus far, six drug clusters (i.e., six types of *drugs*) have been identified, and the patterns of relationships of each cluster of drugs with a set of psychosocial characteristics have been described. At this point, typology of

drug *abusers*, rather than a typology of drugs, was developed empirically by means of proximity cluster analysis. Eight quantitatively and qualitatively distinct types of multiple drug abusers were identified using the standard procedures of Tryon and Bailey's (1970, p. 147) method of iterative condensation on centroids. Of the 440 abuser profiles, 418 were classified into one (and only one) of the eight drug abuser types. The remaining 22 abusers' profiles were too discrepant or unique to be included in any of the eight types.

Thus, independent of their standing on psychosocial variables, eight distinct types of drug users were identified solely by analysis of their standing on the use of the six basic clusters of drugs. Table 4 provides a rough descriptive label for each type of drug user and presents the distinctive profile of the use of the six basic clusters of drugs for each type of user.

Eta statistics in the bottom row of Table 4 indicate the degree to which each of the six drug clusters account for type membership. Conversely, the eight homogeneity statistics indicate the average degree to which membership in each of the eight drug user types specifies scores on the six drug use cluster

score dimensions. All of these statistics are at highly acceptable levels, indicating that the typology obtained possesses a high degree of

statistical integrity and "tightness" (Tryon & Bailey, 1970, p. 161).

Table 5 presents a more complete descrip-

tion of each type, both in terms of drug use patterns and psychosocial characteristics. With drug user type as the independent variable, a series of one-way analyses of variance was performed for each psychosocial variable. Each row of Table 5 represents a significant F ratio of chi-square ($p < .01$) that indicates a significant difference among the eight drug user types on that psychosocial characteristic. The plus and minus entries in each row of Table 5 describe the results of a posteriori multiple-range tests (by the method of least squared differences) that were performed following the significant F test. On any given psychosocial variable, drug user types with a plus sign are relatively high on that characteristic and are significantly different ($p < .01$) from user types with no table entry (who are "average" on that characteristic), who are, in turn, significantly different ($p < .01$) on that psychosocial variable from user types with a minus sign.

Table 5 has been designed to communicate a wealth of significant findings about the characteristics of each type of drug user as directly and completely as possible. The characteristics of each type of drug user suggested by the pattern of findings in Table 5 are briefly summarized below.

Drug User Type 1: Infrequent experimenters. Comprising the bulk of our sample, this type of user has experimented with over 6 different drug classes (of 15 possible) during his/her lifetime and has recently used 1.7 drugs on a regular basis, but is unlikely to have used *any* on a daily basis. This type tends not to use drugs in combinations very often—42% have never consciously used drugs in combinations to achieve an effect.

In contrast to the other types of drug users, these infrequent experimenters feel that they themselves are in control of the direction on their lives. In general, they, their families, and their peer groups are relatively conformist in orientation, and they enjoy a relatively high socioeconomic status. Finally, the infrequent experimenters tend not to use drugs to escape the press of personal problems.

Drug User Type 2: Alcoholics. The alcoholic type of drug user is older, poorer, and

has been convicted of crimes more often (11 times) than any other type of drug user. He or she has had experience with fewer drugs during his/her lifetime than any other type of user (on the average, about three different drugs). The alcoholic type was currently using 1.9 drugs on a regular basis and 1.1 drugs (alcohol) on a daily basis. More than any other type, alcoholics tend *not* to use drugs in combinations, at least not intentionally—65% reported "never" using drugs in combinations to achieve an effect. Alcoholics are relatively conformance oriented in their own values and beliefs, and although they perceive little support for drug use among their peers, they report drinking as one means of conforming to their social group. Compared to any other type of drug user, they recognize fewer drawbacks to their own use of drugs.

Drug User Type 3: Barbiturate and minor tranquilizer users. The user of barbiturates and minor tranquilizers is likely to be an older, white, middle-class housewife who feels powerless to control the direction of her own life. Relatively conformist in orientation, and with the lowest rate of arrests and convictions, the users of barbiturates and minor tranquilizers were the only type of drug users in our sample who had never had *any* experience with heroin or methadone. In regard to the conscious use of drugs in combinations to achieve an effect, 31% of these barbiturate/minor tranquilizer users reported "always" using such combinations. Also, they reported their access to drugs to be easier than any other type of drug user.

Drug User Type 4: Narcotics users. These users of heroin, illegal methadone, other opiates, cocaine, and (in conjunction with these narcotics) hallucinogenic drugs, tend to hold beliefs contrary to the conformist ethos—They are assaultive and tolerant of deviance. The average narcotics user in our sample had been arrested an average of 28 times but had only been convicted three times. They feel that their peers devalue conformance success more than does any other type of drug user. Their use of these "hard" drugs is heavy, and 31% of this type of user report always using drugs in combinations to achieve an effect. In our sample, 57% of

the members of this type were of Mexican-American descent, the only type composed primarily of this ethnic group.

Drug User Type 5: Amphetamines, marijuana, and major tranquilizer users. Users of amphetamines, marijuana, and the major tranquilizers have used more different drugs during their lives (11 drugs); they have used the widest variety of drugs recently on a regular basis (7 drugs); they have used the most different drugs on a daily basis (3.8 drugs); and they are more likely than any other type of user to be using drugs in combination to achieve an effect—73% of these users reported always using such combinations; and none reported “never” using combinations.

These heavy multiple drug users are extremely young, alienated, and assaultive. They are more likely than any other type of user to value drugs as a means of escaping from their personal problems, and they also see drugs as social enhancers and as means of conforming to their social group. In our sample, no member of this drug user type was of Mexican-American descent.

Drug User Type 6: Methaqualone, minor tranquilizer, and barbiturate users. These drug users feel themselves to be in a highly stressful environment while feeling relatively helpless to change the course of their lives. Very unlikely to be extraverted or assaultive, they do not view drugs as a means of “going along” with the group. In fact, they feel that their peer group disapproves of drug use. These users see more drawbacks to their own use of drugs—in terms of loss of self-control, self-respect, and loss of friends—than does any other type of drug user.

Drug User Type 7: Codeine, inhalant, analgesic, and methaqualone users. This type of user tends to use alcohol (to drunkenness) very infrequently, if at all. They are relatively high in socioeconomic status. In our sample, there were no black members of this drug user type, and all members of this type were male. In general, members of this type hold relatively conformist values and attitudes. Their drug use occurs despite their report that (a) they find drugs hard to get and (b) their peers do not support drug use.

Drug User Type 8: Hallucinogenic users.

Primarily users of marijuana and the hallucinogenic drugs (they use more than any other type of drug user), they also are using some amphetamines. These are young, assaultive users, and in contrast to members of Drug User Type 5 (who use many of the same kinds of drugs), they do not feel alienated. More than any other type of user, they reported that their peers are supportive of drug use, and they see the primary function of drug use to be as a means of enhancing social occasions.

Discussion

To return to the three primary aims of this study, six basic classes of drugs were identified empirically. In the present sample, four multiple drug clusters were found, and neither the use of heroin nor alcohol was strongly associated with the use of any other drug.

In general, the four multiple drug clusters found here do not correspond to patterns previously reported in Simpson and Sells's (1974) investigation of the problem of identifying multiple drug abuse patterns among a drug treatment population. In their study of 11,380 patients who were included in the initial 2 years of the National Institute of Mental Health—Texas Christian University Drug Abuse Reporting Program (DARP), 28 distinctive patterns were found. The most frequent pattern, representing over 28% of the patients, was the daily or weekly use of heroin alone. Moreover, daily or weekly use of heroin with cocaine, marijuana, and with both also had prevalent patterns. These four patterns—each involving heroin—accounted for just over 52% of their patients.

There is, however, a major difference between the Simpson and Sells (1974) study and the present one—the differing requirements for admission to the participant treatment programs. The treatment agencies within DARP were primarily treating opiate addicts, and during the first 2 years, users of other drug classes usually were not admitted unless some level of opiate use was also indicated. Thus, given these selection criteria, the finding of a high prevalence of heroin use, singly and in combination, would be

expected. In contrast, the present study contained subjects from a variety of programs, and although 23% were drawn from an alcohol treatment program and 23% from a heroin treatment program, the majority (54%) were from programs not having these selective admission requirements.

In exploring our second objective—the development of an empirical typology of multiple drug abusers—eight distinct types were identified. These types were an intriguing finding, as some of the types, such as Type 1 (marijuana/hallucinogen users), conform to previously reported and commonly described types, whereas other types would not be expected on an *a priori* basis. For example, Type 5 (amphetamine/marijuana/major tranquilizer users) and Type 7 (codeine/nonnarcotic analgesic/inhalant/methaqualone users) are types that are not widely described in the literature.

As with any study of this sort, it should be noted that the typological findings obtained here are functions not only of “real” drug-using phenomena but also of the “method” used to observe those phenomena. Strictly speaking, the present typology must be regarded as a function of the particular drug use measures used, the composition of the sample studied here, and the specific statistical typing procedure used. In this regard, however, the finding of significant degrees of communality between the key C/F measures and other indices of polydrug use (see Table 2), the achievement of a large sample from a variety of drug program sources, and the selection of a well-known standardized set of cluster analysis procedures all suggest that the obtained typology is relatively robust with regard to these method factors.

The third objective was to determine the differential association of a coherent set of psychosocial variables with each of the six drug clusters and the eight drug user types. The particular set of psychosocial measures used in this study is based on social learning theory as articulated by the Jessors and their colleagues, and these measures have been shown previously to be powerful predictors of adolescent deviant behavior. Because the users of the drugs comprising the

third drug cluster (marijuana/amphetamines/hallucinogens) most closely approximate the subject population on which this theoretical approach has been developed, the strong associations of these psychosocial variables with this drug cluster were not unexpected. Nevertheless, if the explanatory scope of the underlying theory were adequate, one would have expected stronger associations with the remaining multiple drug clusters. The general absence of significant relationships between these psychosocial measures and the other multiple drug clusters (particular with Clusters 1 and 5), as well as the striking differences in strength of association, raises questions about the utility of this theoretical approach in explaining a wide variety of multiple drug use patterns. It may be that alternative theories and their associated constructs will be required to provide sets of descriptive variables that relate to differing drug use patterns and users, as has been implied by several recent articles (see Bentler & Eichberg, 1975; Braucht, Brakarsh, Follingstad, & Berry, 1973; Lettieri, 1975; McGlothlin, 1975). On the other hand, it may be that merely introducing key moderator variables or the use of alternative analytic strategies such as those suggested by Gorsuch and Butler (1976) and Dunnette (1975) will reveal additional explanatory power now latent in the present social learning theory.

Although the present study has succeeded in examining specific subgroups of people in relation to specific types of drugs (advocated by Kessler, Paton, & Kandel, 1976), it should be stressed that this study represents an exploratory effort. Future research is needed to build on this step, replicating and extending the present investigation with larger numbers of subjects from differing locales and differing subcultural groups. To provide perspective, a sample of “normals” should be interviewed using the same set of measures employed with drug-abusing groups. There is also a need for further sampling of theories and theoretical constructs in order to provide an arena for the comparative assessment of competing theories in explaining various patterns of multiple drug abuse.

If this line of research were to be pursued successfully, we believe that the resulting

typology would not only contribute to a basic understanding of these problems, but it would also be of great value to those charged with the prevention and treatment of these problems. Given a comprehensive, general typology, *differential* public health programming could be developed for each type of user; the planning, locating, and staffing of these programs could be expected to benefit from the knowledge base provided by a comprehensive typology. Finally, given such a typology, it should be clear that differential evaluations of prevention and treatment programs could be done in a way that is not now possible—Type of program, type of drug user, and their interaction could be examined. Thus, both in terms of pure understanding and practical utility, additional research along the lines of the present study is needed.

Comparative Evaluation of Therapeutic Components Associated With Behavioral Marital Treatments

Gayla Margolin

Department of Education
University of California, Santa Barbara

Robert L. Weiss

University of Oregon

This study investigated the relative effectiveness of three therapeutic components common to behavioral marital therapies: procedures designed to change behavior, procedures to change attitudes, and nonspecific therapeutic effects. A hierarchical ordering of these components produced three treatment conditions—nonspecific, behavioral, and behavioral-attitudinal. Twenty-seven couples experiencing marital distress were randomly assigned to one of the three treatment conditions and one of five paraprofessional counselors. After four therapy sessions, the groups were compared on measures of self-reported satisfaction, daily reported pleasing (or displeasing) relationship events, and observations of communication skillfulness. All groups showed significant decreases in negative relationship behaviors. The behavioral-attitudinal group, compared to the other groups, showed significantly greater improvement in reported marital satisfaction, pleasing behaviors, and positive communication responses.

Comprehensive reviews on the outcome of marital therapies present evidence supporting the efficacy of behavioral strategies to improve marital functioning but caution that much of the evidence is not based on rigorous empirical investigation (Gurman & Kniskern, *in press*; Jacobson, 1978a). The consistently positive findings on behavioral marital therapy come from series of uncontrolled case studies (e.g., Weiss, Hops, & Patterson, 1973) and, more recently, from studies comparing behavioral marital therapy to no-treatment controls (e.g., Jacobson, 1977). Studies comparing behavioral marital therapy to other theoretical approaches provide

more equivocal results (e.g., Liberman, Levine, Wheeler, Sanders, & Wallace, 1976). In both controlled and comparative studies, the utility of behavioral marital approaches is evidenced more consistently on behavioral outcome measures than on traditional self-report measures (e.g., Harrell & Guernsey, 1976).

Overall, the recent proliferation of outcome studies supports the use of behavioral strategies to increase marital accord, but the studies do not identify which ingredients of the behavioral treatment package are responsible for change. For the most part, investigators have applied multiple intervention procedures without using experimental designs that permit identification of the efficacious treatment components. According to Jacobson and Martin (1976), communication skill training and contingency contracting are the two therapeutic elements most commonly used in behavioral marital therapies. However, recent investigations by Jacobson (*in press*) and by Turkewitz and O'Leary (Note 1) suggest that communication training, by itself, may be sufficient to produce marital improvement. The present study was designed as a components analy-

This manuscript was based on the first author's doctoral dissertation, conducted as partial fulfillment of the requirement for the PhD degree at the University of Oregon. The authors thank Ray Hyman, Miriam Johnson, and Edward Lichtenstein for their recommendations and support.

Portions of this article were presented at the meeting at the Western Psychological Association, Los Angeles, April 1976.

Requests for reprints should be sent to Gayla Margolin, who is now at the Psychological Research and Service Center, 734 West Adams Boulevard, University of Southern California, Los Angeles, California 90007.

sis to examine the relative efficacy of therapeutic ingredients associated with communication training in behavioral marital therapy.

The present study served to isolate two features that are typically included in behavioral marital therapies but are not identified as the components that promote therapeutic change. A nonspecific therapy group was included to isolate and control for nonspecific therapeutic effects that accompany and perhaps enhance behavior change technologies. In addition to controlling for standard nonspecific effects, such as relationship and expectancy factors, this nonspecific group also controlled for the unintentional effects related to behavioral assessment procedures. A recent study by Jacobson (1978b) is the only example in which improvement in behavioral therapy clearly is not a function of nonspecific effects: He found that couples who received a behavioral treatment improved significantly more on three out of four outcome measures than couples in a nonspecific control group.

The present study also isolated cognitive restructuring as a potentially active component of behavioral marital approaches. A behavioral-attitudinal treatment was designed that intentionally included procedures to change attitudes as well as procedures to change behaviors. The purpose of the cognitive restructuring procedures was to help spouses reattribute the source of their marital problems to "bad relationship skills" rather than "bad people" in the relationship. When spouses attribute marital difficulty to the personality of the other spouse, they tend to discount that person's attempts to be reinforcing and maintain their pessimistic impressions regarding the relationship (Margolin, Christensen, & Weiss, 1975). The cognitive restructuring procedures in this study were designed to help spouses to (a) be less blaming; (b) become more accepting and responsive to their partners' efforts to be pleasing; and (c) realize that the goal of relationship improvement was mutual, rather than personal, gain. Rather than being a substitute for behavior change procedures, the cognitive restructuring procedures were intended to make it easier for spouses to

engage in behavior change without losing face.

The three treatment conditions in this study systematically introduced therapeutic components to determine the most efficacious combination of components: (a) nonspecific effects (NS condition); (b) behavioral training plus nonspecific effects (BT condition); and (c) attitudinal restructuring plus behavioral training and nonspecific effects (AB condition). It was predicted that couples in the AB condition would experience greater behavioral improvements in their relationships than those receiving the more standard BT treatment. It was also predicted that couples in treatment groups based on social learning theory (AB and BT) would experience greater behavioral improvements in their relationships than couples in the NS group. Since nonspecific effects have been related to more superficial, as opposed to behavioral, changes, it was hypothesized that couples receiving that treatment would make gains, perhaps even equal to the other groups, on the measures indicating self-reported marital well-being.

Method

Design

This research is best conceptualized as an analogue outcome study, since the treatment offered was an intensified, abbreviated, and standardized version of naturalistic therapy. Treatment parameters not salient to the behavioral or cognitive components were constant across treatment groups, for example, number of sessions and amount of therapist contact. Spouses were seen conjointly at weekly intervals by their own individual therapist over a period of 4 weeks for a total of four 2-hour sessions. The fixed treatment sequence consisted of a (a) 1-week baseline evaluation; (b) 2-week intervention phase; and (c) 1-week posttreatment evaluation. Each couple was randomly assigned to one of the three treatment conditions and to one of five paraprofessional counselors for 4 weeks of couples counseling.

Subjects

Twenty-seven couples experiencing marital distress participated in the study. Although couples were recruited through publicity on radio, television, and in the local newspapers, acceptance into this project was based on evidence of marital distress. Marital distress was initially assessed by the experimenter in a tele-

phone interview and a 1-hour intake session. In addition, couples had to meet two of the following three criteria to be accepted into the project: (a) a mean spouse Locke-Wallace score < 100 ; (b) a total couple Areas of Change score > 15 major problem items; and (c) a therapist rating < 4 based on an 8-point rating scale ranging from high marital distress to high marital adjustment. The mean spouse Locke-Wallace score of participating couples was 71.8 ($SD = 22.5$). Of the 31 couples who volunteered for the project and who completed screening procedures, 2 couples did not meet the criteria for marital distress, 1 couple declined treatment, and 1 refused treatment after the first session. Upon entering counseling, all couples paid a \$50 refundable security deposit that was contingent on keeping scheduled appointments and completing homework assignments. The total deposit was refunded to all except 1 of the 27 participating couples.

Client couples varied substantially in age (range from 20 to 72 years; $Mdn = 31.5$) and income (range from \$3,500 to \$27,000; $Mdn = \$15,000$), and had a relatively high education level. (For 19 couples, one or both spouses had obtained a college degree.) Seven of the couples were childless, but overall the sample averaged 1.4 children per family. For 11 of these couples, one or both partners had been engaged in prior therapy. Analyses of variance were used to examine possible group differences in age, length of marriage, number of children, and income; no significant between-group differences were found.

Therapists

Of the five persons serving as paraprofessional therapists,¹ two had completed college and three were undergraduates. Since none of the therapists had previous experience in counseling couples, they all underwent 40 hours of training prior to seeing their first cases and continued to participate in both group and individual supervision during the time they saw cases. All training and supervision was conducted by the first author.

Measures of Treatment Validity

Two measures were designed to assess the credibility of the major assumptions behind the experimental design that (a) treatment modalities were equally believable and (b) nonspecific couples without specific training would not be knowledgeable about principles of social learning theory applicable to marital problems. A posttest treatment evaluation questionnaire, designed to measure satisfaction with treatment, tested the first assumption. The Consultation Readiness Inventory, consisting of multiple-choice questions following brief vignettes of marital conflicts (similar to the Inventory of Marital Conflicts by Olson & Ryder, 1970), was used to measure spouses' knowledge of and capacities for applying behavioral principles. Spouses independently read the vignettes of hypothetical marital problems and identified the statement that best described factors contributing to each problem and/or strategies for remedying each problem.

Measures of Treatment Outcome

Multidimensional outcome criteria were used to determine how the separate therapeutic components contribute differentially to specific outcomes. Six distinct measures were used: three self-report inventories, two daily reported observational indices from the home, and observational data from videotaped interactions in the laboratory.

Self-report satisfaction inventories. Three questionnaires were used to measure global marital satisfaction of spouses prior to the first session and after the final session. The Locke-Wallace Marital Adjustment Inventory (Locke & Wallace, 1959), which was chosen for its wide usage in traditional marital literature, provides an index of marital compatibility and stability. The Areas of Change Questionnaire (Weiss et al., 1973) provides an index for measuring the amount of change that each spouse desires in the partner's performance of specific relationship behaviors. This 34-item inventory asks each respondent to indicate on a 7-point scale whether (a) she/he desires the spouse to change a particular behavior and (b) it would please the partner if the respondent were to change. Each spouse also completed the Adjective Check List (Gough & Heilbrun, 1965) indicating which adjectives accurately described the partner, thereby capturing the evaluative trait labels that spouses cognitively assign to one another.

Daily reported home observations. Every evening throughout the 28 days of treatment, each spouse recorded the number of pleasing and displeasing relationship events that she/he received from the partner as well as the frequency of pleasant thoughts that she/he had about the partner. Pleasing and displeasing behavioral events were recorded by means of the Spouse Observation Checklist (SOC; Weiss et al., 1973; Weiss & Margolin, 1977), which provides 400 sample relationship behaviors representative of 12 areas of marital functioning (e.g., communication, affection, companionship). The specific behaviors have either a pleasing (e.g., "Spouse gave me a massage") or displeasing (e.g., "Spouse criticized me") effect on the recipient. Each spouse also recorded the occurrence of pleasant thoughts about the partner on a tracking card.

Laboratory observational data. During the first and last sessions, each couple engaged in two 10-minute negotiation sessions during which the spouses attempted to solve a relationship problem without any interruptions or assistance from the therapist. Topics for both negotiation sessions were chosen by the couple before they began the discussions. Therapist instructions specified that the couple was to act as they would normally and to problem solve as best they could. These negotiation sessions were videotaped and then coded by trained observers using the Marital Interaction Coding System (MICS; Hops, Wills, Pat-

¹ The therapists were Bark Brasted, Katherine Engel, Kenneth Freedland, Debra Jackson-Spangler, and Jan Robertson.

terson, & Weiss, Note 2), a 29-category observational system that provides a sequential accounting of verbal and nonverbal communication processes. Validation of the MICS comes both through treatment studies, which demonstrated that the MICS was moderately sensitive in discriminating preintervention to post-intervention changes (Patterson, Hops, & Weiss, 1975), and analogous studies, which demonstrated that the MICS accurately discriminated couples who defined themselves as distressed or nondistressed (Birchler, Weiss, & Vincent, 1975). MICS coders were undergraduates, who were trained for a total of 20 hours or until they reached the minimum criterion of 70% reliability. Coders worked in pairs, and two pairs coded each 10-minute segment. To calculate percentage of agreement, one coder was randomly chosen to be "calibrator." The total frequency of agreements between coders was divided into the total number of codes recorded by the calibrator; that is, agreements plus disagreements. This quotient was then multiplied by 100. Any observation that did not reach the criterion of 70% reliability was recoded by another coder pair. High interobserver reliability was maintained by once per week random spot checks on individual coders.

Intervention

Communication training. The main therapeutic purpose of all three treatment conditions was to improve communication skills. The general structure used by all groups consisted of 10-minute negotiation discussions, during which spouses attempted to resolve a conflictual issue, and 10-minute feedback periods, during which spouses shared reactions to the process of the preceding negotiation discussion. Each 2-hour therapy session included four negotiation sessions interspersed with four feedback discussions. Specific procedures used during the negotiation and feedback discussions varied according to group assignment.

Communication training for the BT group incorporated principles common to many behavioral marital treatments, namely that spouses must (a) explicitly define (pinpoint) specific behaviors that the partner is to accelerate and then (b) faithfully reinforce the occurrence of these behaviors. The specific behaviors to be increased were "helpful" communications, which were operationally defined by the partitions. During each negotiation discussion, one spouse was designated as the "sender" and the other as the "receiver" of helpful communications. While attempting to resolve a problem issue, BT couples used an electromechanical apparatus to increase the rate at which the sender emitted helpful responses.

The electromechanical apparatus consisted of (a) a raucous buzzer functioning as a negatively reinforcing stimulus and (b) a pleasant single-tone chime functioning as a reward. The buzzer was activated by a recycling interval timer, which timed an interval of 1.75 minutes. The spouse designated as receiver of coded, by means of a silent hand-held button, each time the sender emitted a helpful response. Each cod-

ing of a response (a) activated the pleasant chime signaling to the sender that she/he had been helpful and (b) reset the timer to postpone the buzzer. If the 1.75 interval expired without a helpful response, the timer activated the buzzer, signaling to the sender that she/he must emit a response to terminate the buzzer. Spouses alternated roles for each new 10-minute negotiation discussion. During the feedback periods, the receiver for the previous discussion identified which behaviors the sender was to accelerate. The sender then rehearsed unfamiliar responses before his/her next trial as sender. In these BT procedures, each spouse identified what the partner could do to increase communication helpfulness.

In the AB condition, spouses also defined behaviors that they wanted accelerated. However, only those behaviors agreed on by both partners were accepted as targets for change. This strategy was adopted to avoid the problems that arise when one spouse demands a change that the other is reluctant to make. In a manner similar to BT couples, AB couples used the electromechanical apparatus and alternated between sender and receiver roles. The difference, however, was that AB couples worked to increase the rate at which they agreed on the coding of helpful responses rather than to increase one spouse's output of these responses (cf. Margolin & Weiss, in press). In the AB condition, both spouses simultaneously coded helpfulness. The sender coded helpful behaviors that she/he emitted, and the receiver coded the sender's behaviors that were perceived as helpful. The goal of the exercise was to increase sender-receiver agreements, which were defined as simultaneous responding by both partners within a 2-sec interval. Each of these agreements activated the chime and reset the buzzer. During feedback periods, AB spouses identified which communication behaviors they had jointly defined as helpful and then pinpointed and rehearsed these behaviors. Success on this task was labeled as couple agreement; that is, the spouses held congruent perceptions about the process of their communication even though they were still in conflict over content issues.

NS communication training followed a similar structural format of negotiation and feedback discussions but lacked specific behavioral training. During the negotiation discussions, spouses did not use the electromechanical cuing apparatus, nor were they in sender-receiver roles. Instead, they engaged in uninterrupted 10-minute discussions that focused on a relationship problem. During the feedback period, the therapist encouraged the spouses to express feeling statements and discuss perceptions but discouraged prolonged discharge of pent-up emotion. Rather than helping spouses to define specific behaviors, the therapist directed his/her activity toward the reflection and acceptance of each spouse's feelings.

Increasing the pleasing behaviors. The secondary therapeutic purpose across treatment conditions was to generate immediate gratifications for couples to offset the tedium of communication skill training. This treatment goal was achieved through homework assignments using the SOC. NS couples continued to

use the SOC in the same manner as all couples had done during the assessment phase. Each evening, NS spouses indicated which pleasing and displeasing items had occurred during the previous 24-hour period. In addition to tracking those events, each spouse in the BT group pinpointed desirable events on the SOC and worked toward a 100% increase in his/her output of those events that the partner had identified as pleasing. AB couples first agreed on a subset of events that they both identified as pleasing and then worked as a team toward a 100% increase in the identified couple pleasing behaviors.

Reading assignments. Assignment of the following readings lent rationale and credibility to the procedures for each group: NS couples read a chapter from Lederer and Jackson's (1968) *Mirages of Marriage* about communication in a marital relationship. BT couples read Chapter 2 from a manuscript by Weiss and Ford (Note 3) that defines behavioral principles, such as pinpointing, reinforcement, and shaping and demonstrates how these principles apply to marital interactions. AB couples read Chapters 1 and 2 of the Weiss and Ford manuscript; Chapter 1 describes how unsatisfying relationships are a function of poor relationship habits rather than either spouse's bad intentions.

Cognitive restructuring. In addition to the other therapeutic components, AB treatment included procedures to modify spouses' cognitions regarding the source of their marital discontent. The cognitive restructuring component, which was conveyed through therapist explanations and readings, contained the following messages: (a) Blame does not reside with one or the other spouse; (b) both persons suffer as participants in a dysfunctional relationship; and (c) frustration from feeling powerless to improve the relationship is often confused with resentment toward the spouse. Spouses were encouraged to apply non-blaming explanations to situations in which the partner's behavior was perceived as undesirable.

Results

Validity of Treatment

Two inventories completed at the conclusion of treatment provided an internal validity check on whether the treatment conditions captured the intent of the experimental design. A one-way analysis of variance of the Posttreatment Evaluation Questionnaire, which measured consumer satisfaction, revealed no group differences in how couples perceived or evaluated the different treatment modalities. The Consultation Readiness Inventory provided information on the dual questions of (a) whether couples in both behavioral groups were adequately instructed in social learning theory principles and (b)

whether, in fact, couples in the nonspecific group were privy to the same social learning theory information provided to the two behavioral groups. Findings on this inventory also confirmed design expectations. Mean item scores for behavioral (22.44) and behavioral-attitudinal (22.11) couples were significantly higher than the scores for nonspecific couples (12.22), $F(2, 24) = 11.06$, $p < .01$.

Outcome Criteria

Each outcome variable was analyzed for within-group and between-groups changes. Separate matched-pair t tests were used for within-group analyses to determine pretreatment to posttreatment changes for each group on each variable. Given the large number of analyses generated by this statistical approach, any particular test meeting the .05 level of statistical significance must be interpreted cautiously. The relative effectiveness of different treatment conditions was examined by between-groups analyses. Covariate procedures were used on all between-groups analyses to control for differences in prescores on each measure. Planned-comparison t tests on the adjusted posttreatment means were used when between-groups differences had been predicted; analysis of covariance was applied when there were no such predictions. In each statistical analysis, couples were analyzed as units; couples' scores were either the sum or the average of husband-wife scores.

Self-report satisfaction inventories. Table 1 presents the results for the four self-report measures. Within-group effects were measured by comparing pretreatment and posttreatment scores, obtained prior to therapist contact and after the posttreatment assessment week; t values are presented for pretreatment to posttreatment comparisons. Between-groups effects were examined through the adjusted posttreatment means.

The within-group marital satisfaction scores on the Locke-Wallace revealed that both the AB and the NS groups reported significantly increased satisfaction. In addition, significant between-groups differences were

found for adjusted posttreatment means, $F(2, 23) = 3.59$, $p \leq .05$; a post hoc Scheffé analysis on these data supported the conclusion that the AB group's posttreatment scores were significantly higher ($p < .05$) than those of the other two treatment conditions.

A similar pattern of results was obtained for the Areas of Change Questionnaire: Only the AB group significantly reduced total conflict scores from pretreatment to posttreatment measurements. Since all groups improved, between-groups differences were not significant.

The Adjective Check List results were examined by separate analyses of mean frequencies of checked positive and negative adjectives. The AB group significantly reduced their mean frequency of negative labels, although the mean frequency of positive

labels remained the same. The BT group reduced the frequency of both negative and positive adjectives, perhaps reflecting a tendency to use all trait labels less often. Couples in the NS group did not change from baseline rates on either adjective measure. No between-groups differences were found for mean frequencies of either positive or negative adjectives checked.

Overall, the AB group, relative to the other groups, consistently demonstrated a greater degree of improvement on the three self-report measures. Contrary to prediction, reported marital satisfaction as evidenced on the Locke-Wallace, increased in only two of the three groups.

Daily reported home observations. Spouses recorded daily pleasing and displeasing events received from the partner, that is, SOC items, as well as pleasant thoughts

about that person. The AB and BT groups were expected to demonstrate greater improvements than the NS group, and the AB group was expected to display greater improvement than the BT group. Separate planned-comparison *t* tests were used to analyze these directional predictions.

Table 2 presents mean daily spouse pleasing, displeasing, and pleasant thought totals. Since the data were collected throughout treatment, the table also includes midtreatment scores averaged across the 14-day intervention. The pretreatment and posttreatment means are for 5 and 7 days, respectively, of data collection.² Pleasing events were explicitly increased as an intervention strategy in both behavioral groups thereby limiting the utility of recorded pleasing behaviors as an index of treatment outcome. This measure assesses (a) whether clients had followed the instructions to increase pleasing events during intervention and (b) whether these behavior changes were maintained after the instructions had been withdrawn.

During intervention both behaviorally oriented groups increased their mean daily

rates of pleases approximately 43% over their baseline rates. At posttreatment assessment, the AB group further increased its mean rate of pleasing behaviors, whereas the BT group merely maintained its intervention rate. Only the AB group demonstrated significant pretreatment to posttreatment change in rates of pleasing behaviors. Planned-comparison *t* tests confirmed the prediction that both behavioral groups would exchange more pleasing events than the NS group, $t(23) = 2.15$, $p \leq .025$. Examination of rates of displeasing behaviors revealed results unlike those for pleasing behaviors; the mean daily rate of displeasing behavior decreased significantly for all three groups.

The cognitive restructuring procedures were expected to produce significant increases in spouse-related pleasant thoughts. The AB group confirmed this expectation. Even though the other groups showed

² Data from the first 2 days of pretreatment were discarded because of their excessive variability for all groups.

changes indicating improvement, they were not significant.

Results of the daily recorded home data suggest that pleasing and displeasing behaviors were differentially effected by the treatment components. All groups displayed decreases in displeasing behaviors that were not even the target of any specific intervention technique. Yet increases in pleasing behaviors occurred only when there was a direct intervention to change those responses; merely tracking the occurrence/nonoccurrence of pleasing behaviors was not associated with changes in reported frequency of those behaviors.

Laboratory observational data. Communication skillfulness was assessed by MICS coding of two pretreatment and two post-treatment 10-minute videotaped samples of each couple negotiating a relationship problem. Average point-by-point observer agreement for the 108 coded samples was 83.8%. Coding was reduced to two summary scores for purposes of data analysis: positive responses (agree, approval, accept responsibility, compromise, humor, problem solution, attention, assent, laugh, positive physical contact, and smile) and negative responses (complaint, criticize, deny responsibility, excuse, no response, not tracking, put down, and turn off). Neutral behaviors such as

unfocused problem description were not included in the analyses. To control for differences in individual activity rates, each of these summary categories was expressed as the proportion of total responsiveness; individual husband and wife proportions were averaged for the couple score.

Table 3 provides pretreatment, posttreatment, and adjusted mean proportion scores for MICS coded positive and negative responses. Only the AB group significantly increased positive communication skills between pretreatment and posttreatment measurements. The mean increase in the positive response proportion was approximately 35% over baseline for the AB group, as compared to 9% and 20% increases for the BT and NS groups, respectively. A planned-comparison *t* test for between-groups measures revealed that the AB group increased significantly more than the BT group.

The between-groups differences found with the positive communication score were not paralleled with the negative communication score. Regardless of treatment mode, all groups reduced their mean proportion of negative behaviors to less than 50% of their baseline levels. The magnitude of these reductions was comparable for all treatment groups.

These results are consistent with the find-

Table 3
Treatment Effects on Laboratory Observational Data (Mean % Positive and Negative MICS Scores)

Dependent variable	Pretreatment		Posttreatment		Pre-Post <i>t</i>	Between-groups adjusted posttreatment <i>M</i>

NS	11.30	6.30	5.50	4.38	4.21***	5.26

Note. BT = behavioral training plus nonspecific effects; AB = attitudinal restructuring plus behavioral training and nonspecific effects; NS = nonspecific effects.

* AB score is significantly higher than the BT score.

* $p \leq .05$, one-tailed.

** $p \leq .025$, one-tailed.

*** $p \leq .005$, one-tailed.

ings for SOC pleasing and displeasing behaviors; the between-groups difference for increases in desirable behaviors demonstrates strong support for the inclusion of the additional features of attitudinal restructuring. Reductions in negative responses do not appear to be related to specific therapeutic procedures, since all treatments were equally effective in producing a decrease in these behaviors.

Summary of Results

Overall, nine outcome measures spanning three modes of observation figured into the within-group and between-groups analyses. Out of the nine within-group *t* tests, the AB, BT, and NS groups showed significant changes in the predicted direction on 8, 3, and 3 measures, respectively. Significant between-groups differences were found on the following three outcome criteria: Locke-Wallace scores, SOC pleasing behaviors, and MICS positive behaviors. The AB group displayed significantly greater improvement than the BT group on the first and third measure and greater improvement than the NS group on the first measure. Thus, the AB group demonstrated significantly greater improvement than one or both of the other groups on at least one measure in each assessment mode.

Discussion

This study presented a method for implementing a therapeutic intervention for marital distress while maintaining careful control over the application of specific treatment procedures. Although a representative clinical sample was used, the following features of the study limit its applicability to naturalistic behavior marital therapy: (a) a highly abbreviated intervention period; (b) inexperienced paraprofessional therapists; and (c) highly standardized procedures. Because of the abbreviated nature of the intervention, the results of this study reflect changes that would occur during the initial stage of a standard course of therapy. It is as yet undetermined whether the demonstrated improvement would persist over time. Due to clinical considerations, follow-up data

were not collected to examine the maintenance of treatment effects. Since couples in this study received only a portion of a complete treatment, they were offered additional counseling through a marital treatment group. Follow-up data on the original study would have been confounded by this additional treatment, since only a portion of the couples participated in these groups and the participating couples joined the groups at different times after completing the original treatment.

The purpose of this study was to explore how specific therapeutic components differentially effect the initial stage of behavioral marital therapy. The results of this study revealed two predominant trends. Couples in the AB group, who received all three of the identified therapeutic components, consistently demonstrated greater improvement than couples in the other treatment groups. However, this finding applied only to criteria measuring change in a positive direction, that is, the measurement of attained relationship benefits. Criteria measuring dysfunctional coupling behaviors revealed significant reduction for all treatment groups; the treatment groups were not differentially effective in lessening problematic relationship behaviors.

There are several explanations to account for the reduction in negative behaviors displayed by all treatment groups. First, it is possible that demand characteristics associated with entering counseling heighten the level of negativity displayed at that time. Negative MICS behaviors would be high if spouses entered therapy with the notion that therapy is a time to argue and air grievances. The negative behaviors might then lessen over the weeks if the therapist did not reinforce these behaviors or if the spouses themselves grew tired of these unproductive patterns. Likewise, SOC displeasing behavior would be high if spouses used that instrument as a vehicle to demonstrate to the therapist the faults of the partner. SOC displeasing behavior might also decrease once the therapist communicated that she/he understood what each spouse was experiencing. Second, since the NS group received the same assessment procedures as the other

treatment groups, the reductions in negative behaviors displayed across all three groups may be indicative of clients' reactivity to the behavioral assessment procedures (cf. Johnson & Bolstad, 1973; Jones, Reid, & Patterson, 1975). That is, spouses' knowledge that their behaviors were being observed may have motivated them to reduce their negative behaviors in an effort to avoid censure by the partner or therapist. Unfortunately, reactivity to observations by the partner (on the SOC) or the therapist (through the MICS) cannot be distinguished from other nonspecific effects. It is interesting to note, however, that the data do not support an interpretation of similar reactivity in the positive direction; that is, spouses in the NS group did not increase positive or facilitative behaviors.

In light of more positive outcome literature on behavioral marital therapies (e.g., Jacobson, 1977; Weiss et al., 1973), what accounts for the BT group's relative ineffectiveness in this study? The brevity of the treatment may be one explanation; although the cognitive component appears to generate more rapid improvement, standard BT therapy might produce the same changes over a normal course of therapy. Second, the experimental design of this study excluded all cognitive restructuring factors from the BT group. Perhaps the systematic elimination of cognitive restructuring features in the BT treatment actually removed a competent that is typically included in behavior therapy under the rubric of reeducation or therapist persuasiveness. Most writings about behavioral treatments emphasize specific behavioral techniques and take for granted the procedures used to help clients generate a cognitive set that facilitates behavior change. Even though this study illustrates the pitfalls associated with behavioral training conducted in the absence of adequate cognitive preparation, more careful description of therapeutic procedures is needed to determine the extent to which behavior therapists currently use cognitive restructuring procedures.

Overall, the results of the present study suggest that the combination of the three identified therapeutic components in the AB

group provided an effective method to control aversive exchanges as well as an increase in rewarding marital interactions. These results pose the question as to which aspect of the cognitive restructuring component made the AB treatment more effective than the BT treatment. The two cognitive restructuring features that differentiated the AB from the BT treatment were (a) the modification of therapeutic exercises to focus on mutual rather than individual goals and (b) the reattribution message conveyed through readings and therapist instructions. Anecdotal feedback from clients suggested that the focus on mutual goals was helpful for distressed spouses who were reluctant to engage in behavior changes requested by the partner. The mutual goal setting allowed each spouse to exercise more control in defining the behaviors that she/he was to change. However, for spouses who share very few common goals, the mutual focus may limit the scope of therapeutic change and impede overall progress.

Cognitive restructuring within a marital therapy framework provides the most innovative aspect of the AB treatment. Recently, a number of investigators working on a variety of problem areas (cf. Mahoney, 1974; Meichenbaum, 1977) have used cognitive restructuring procedures to reduce the incapacitating emotions that tend to accompany dysfunctional behaviors, making those behaviors resistant to change. The cognitive component in this study was an initial attempt in using cognitive restructuring procedures to interrupt the negative thoughts that can impede relationship improvement. The therapeutic procedures encouraged spouses to abandon blaming attributions, to accept greater personal responsibility for relationship failure, and to be more accepting of their partners' positive efforts. This approach, which is somewhat similar to Ellis' (1962) rational-emotive psychotherapy, was expected to decrease the likelihood of mislabeling ambiguous behaviors or overresponding to negative relationship exchanges. The reattribution procedures in this study were presented in a standardized fashion that disallowed their being tailor-made to a couple's particular needs. Furthermore, no attempt was made to

rehearse the cognitive restructuring materials or to monitor how spouses used them. Nonetheless, the encouraging findings for the AB treatment strongly support the application of cognitive restructuring procedures to reduce spouses' blaming attributions and to foster prerequisite attitudes for constructive problem solving.

Bias or Artifact? A Reply to Reade and Wertheimer

David J. McDowell

University of Maine and Worcester State Hospital, Worcester, Massachusetts

In a recent *Journal of Consulting and Clinical Psychology* brief report, Reade and Wertheimer reported an analogue study of the diagnosis of schizophrenia and inferred from their data that diagnosticians' judgments of the probability of schizophrenia are biased inappropriately by the information that a patient has an identical twin diagnosed as schizophrenic. In rebuttal, it is argued that the procedures used in that study compelled the diagnostic behavior that the authors criticized and that the implicit generalization from this analogue study to reasonable clinical practice was unjustified.

Reade and Wertheimer (1976) reported an analogue diagnostic study in which a brief case description was given to two groups of clinical judges who rated the probability that the fictitious patient was schizophrenic. The two case descriptions differed only in their second sentence, which stated either that "Mr. S has an identical twin, who 7 years ago joined the army and has visited home only once for a 2-week long stay" (p. 878), or "Mr. S has an identical twin, who 4 years ago was placed in a mental hospital with a diagnosis of simple schizophrenia" (p. 878). The remainder of the case study described parental roles (father was domineering and quick-tempered; mother was attentive and spoiling), emphasized the patient's poor interpersonal relations (introverted, shy with girls, few close relationships), and referred to some possibly symptomatic behaviors (refusing to speak to his father for several days after his father berated him for not looking for a job, apathy, and "a slow but pronounced change in his character," which included untidiness, neglect of personal appearance, "strange" behavior at his father's funeral, and frequent change of jobs due to poor peer relations and malingering). The clinicians who read that Mr. S had a schizophrenic identical twin rated a mean probability of schizophrenia of .66, whereas the clinicians who read that Mr. S's twin

had joined the army rated a mean probability of schizophrenia of .39. The two groups' ratings differed significantly ($p < .01$) by a Mann-Whitney U test, and the authors concluded that the information that Mr. S had a twin diagnosed as schizophrenic was responsible for this difference.

Should such information increase the clinician's likelihood of diagnosing a patient as schizophrenic? Reade and Wertheimer (1976) argued that diagnosis "should ideally be based on an analysis of individuals' . . . behavior . . . [and not on the] knowledge that a predisposition to schizophrenia may be inherited." They concluded that

prior to availing themselves of family history, diagnosticians [should] attempt to obtain relatively conclusive behavioral information, lest they inadvertently increase the likelihood of a diagnosis of psychopathology where none exists" (p. 878).

Although this argument and conclusion are sound, neither is relevant to the data reported.

In this study, clinicians (a) were not permitted to observe the patient's behavior; (b) were given pertinent family history before, and instead of, good behavioral records; and (c) were asked to indicate the probability of a specific diagnosis rather than make their own diagnosis in a free-response format. The procedures used in the study thus compelled the clinical-diagnostic behavior that the investigators then decry!

What the reported data *do* indicate is that in the absence of direct observation or good be-

havioral records, and with an extremely restrictive set of data from which to assess the probability of a specified diagnosis, these clinicians attended to a relevant family history variable that has been shown to correlate significantly with the diagnosis in question. Reade and Wertheimer implied that the diagnostic judgment of these clinicians was biased by nonbehavioral data. On the contrary, their experiment demonstrates (a) that clinicians are aware of the significant concordance rates for schizophrenic identical twins and their undiagnosed probands and (b) that

the analogue study of diagnostic judgment may differ sufficiently from reasonable clinical practice that generalization to the latter is unjustified.

Psychometric Phrenology Revisited: Comments on Neuropsychological Testing

Steven Waksman

Multnomah County School Mental Health Program
Portland, Oregon

Amante, Van Houten, Grieve, Bader, and Margules' interpretation of results obtained from testing third-grade children with the Bender-Gestalt Test, the Frostig Developmental Test of Visual Perception, and the Wepman Auditory Discrimination Test is critically evaluated. It is pointed out that such tests not only lack empirical and linguistic validity, but they also tend to confuse their users and often hamper more appropriate remediation services to children with learning disabilities. The continued support of such tests is questioned.

In a recent article in this journal, Amante, Van Houten, Grieve, Bader, and Margules (1977) described the racial and socioeconomic differences obtained on commonly administered tests of perceptual functioning. Although the article raises some important and interesting issues concerning environmental factors related to neuropsychological functioning, it unfortunately stumbles into the logical abyss occupied by much of the literature concerning learning disabilities and neurological deficits.

The authors tested

a random sample of 225 third-grade public and parochial school children of both sexes representing a cross-section of subjects drawn from all of the major ethnic groups and socioeconomic levels" (Amante et al., 1977, p. 525)

present in their community. The results indicated that between 40%-60% of the sample exhibited "evidence" of perceptual-motor, visual-perception, and auditory discrimination handicaps as measured by the Bender-Gestalt Test, the Frostig Developmental Test of Visual Perception, and the Wepman Auditory Discrimination Test, respectively. The authors then proceeded to interpret such results as indicating neuropsychological deficits and discussed the implications of the ethnic and socioeconomic differences.

I wonder how psychologists and educators can continue to support the use of these tests for diagnosing neuropsychological problems when

they identify 40%-60% of randomly selected children as neuropsychologically handicapped or impaired. Undoubtedly, the vast majority of these "handicapped" children were functioning appropriately or excelling both academically and socially in their environments. The lack of linguistic (Payne, 1975) and empirical (Anderson, 1965; Blakemore, 1965; DiCarlo, 1965; Goldberg, 1959; Larson, Rogers, & Sowell, 1976) validity of such widely used instruments is appalling. As Jastak and Jastak (1976) have pointed out, not only are such tests poorly conceived and validated, but in reality they "convey no meaningful information" and only tend to confuse their users as well as the teachers and parents of the children on whom they are used.

This process is witnessed all too often by school personnel who refer students with learning problems for evaluation and recommendations. The evaluation reports that often return with the referred student describe perceptual deficits or handicaps as the "cause" of the learning problem. According to the Amante et al. (1977) data, every third-grade child has a 40%-60% chance of being diagnosed as perceptually handicapped. To confound the issue even more, there is a myriad of perceptual training programs available that offer no research support for their effectiveness (McIntosh & Dunn, 1973) and that often stand in the way of appropriate remediation attempts (Mann, 1970). In short, as Mann (1971) has previously argued, such "psychometric phrenology" and the perceptual training programs that often follow such ability assessment offer little more than the "philosophies of faculty psychology."

Requests for reprints should be sent to Steven Waksman, 2242 Northeast 21st Avenue, Portland, Oregon 97212.

Although perceptual problems are often a correlate of neurological impairment (Chalfant & Scheffelin, 1969; McIntosh & Dunn, 1973), the converse of this is not necessarily true. Learning problems may result from many factors (Eichenwald & Fry, 1969; Jastak & Jastak, 1976; McIntosh & Dunn, 1973; Moyer & Newcomer, 1977), and there is still no evidence as yet (Goodman, 1977) that neurologically impaired children (except in very rare cases) should be taught any differently from nonimpaired children.

The time has come for us to stop blaming children for their lack of academic achievement, to stop scaring parents with brain-damaged labels, and to start sweeping the field of learning disabilities clear of faulty measurement and foggy logic.

Response to Psychometric Phrenology Revisited: Comments on Neuropsychological Testing

Dominic Amante

West Shore Mental Health Clinic, Muskegon, Michigan

Steven Waksman has raised some controversial issues in his critique of a neuropsychological study. The study dealt with the ecological distribution of central nervous system pathology in working class and socially disadvantaged black children and white children. Some of the issues that Waksman raises can be resolved, at least partially, but others cannot because of the fact that basic differences of opinion continue to exist in the absence of uncontested theory and decisive empirical data.

Waksman (1978) has raised some vital issues in his critique of a neuropsychological field study that we reported in this journal recently (Amante, Van Houten, Grieve, Bader, & Margules, 1977). Unfortunately, he has also introduced a variety of irrelevant issues.

It is important to observe that Waksman's critique is highly selective. For example, it does not deal with the intelligence test results. Consequently, it fails to refer to perhaps the most positive feature of the Amante et al. study—namely, the possibility that there are no differences in the levels of general intelligence or auditory discrimination in black children and white children of comparable socioeconomic status when the level of visual-motor functioning is controlled. His interest is in deficit conditions only, but even in this case he misrepresents our data and overgeneralizes the conclusions.

Based on an extensive clinical and research tradition, many medical and behavioral scientists have concluded that various forms of mild or severe neuropathology measurably influence a broad spectrum of psychological functions including language development, affective states, perceptual-motor skills, cognitive abilities, and various other behavioral parameters (Dimond & Beaumont, 1974; Reitan, 1975; Strub & Black, 1977). Consequently, there is no essential reason to conclude, as does Waksman, that the majority of perceptually impaired children were adequately functioning in their environments. Per-

formance on the Bender-Gestalt, for example, does relate to nontest factors such as school readiness, intellectual level, academic achievement, emotional and behavioral problems, and many diverse forms of neurological pathology (Koppitz, 1975).

It is doubtful if the test instruments that were used are as psychometrically unsophisticated as Waksman and others would have us believe. In fact, such techniques may be preferable considering the reliability and validity of simple behavioral observation, subjective impression, or "clinical intuition" (Korchin, 1976; Landy & Trumbo, 1976). It is true that modern medicine has been unable to devise neurodiagnostic techniques of perfect reliability and validity (Kennedy & Ramirez, 1964), and as nearly everyone now realizes, psychologists and educators have no instruments that are diagnostically impeccable (Anastasi, 1968). There is, however, a plausible rationale behind neuropsychological assessment (Boll, 1977), but in all cases we necessarily deal with diagnostic probabilities—not certitudes (Amante, 1976).

Some other issues should be considered. Waksman's (1978) primary interest appears to involve learning disabilities and related problems as well as tertiary prevention, which Caplan (1964) defines as an attempt to reduce the residual defect(s) associated with various conditions of physical and behavioral pathology. However, Amante et al. (1977) dealt with more general issues involving a diversity of neuropsychological outcomes, and the central thrust of the article pertains to primary and secondary prevention. That is, our basic concern involved the identification of environmentally based etiological factors, the control of which may reduce

Requests for reprints should be sent to Dominic Amante, West Shore Mental Health Clinic, 2525 Hall Road, Muskegon, Michigan 49442.

the incidence and the prevalence of central nervous system pathology in children.

It is conceded that the differential diagnosis and treatment of learning disorders and related problems is a controversial area (Larsen & Hammill, 1975; Ross, 1976; Spache, 1976). The interesting point that Waksman (1978) overlooks, however, is that it is also true that many of the leading theoreticians and researchers in the field believe that most (if not all) learning-disabled children are neurologically impaired, that they frequently do appear to have perceptual-motor and behavioral problems, and that various specialized educational methods individualized for the child often are called for (Cantwell, 1975; Johnson & Myklebust, 1967; Kenny & Clemmens, 1971; Kephart, 1969; Myers & Hammill, 1976; Reitan & Boll, 1973). William M. Cruickshank's (1972) position is not atypical:

I would like to suggest . . . that irrespective of the presence or absence of diagnosed neurological dysfunction, learning disabilities are essentially and almost always the result of perceptual problems based on the neurological system (p. 383).

Finally, it should be recognized that Waksman (1978) seems to assume the empirical viability of labeling theory (Scheff, 1975) even though many sociologists, who created the theory, have seriously questioned the validity of the approach (Gove, 1975). I agree that it is imperative from an ethical and a diagnostic point of view to exercise extreme caution when classifying children (Hobbs, Egerton, & Matheny, 1975), but if actual problems appear to be present, the diagnostician has an obligation to confront the situation and to devise a rational intervention strategy. We are not helpful to children if we evade our diagnostic responsibilities with the vague claim that somehow the diagnostic label creates more problems than it resolves. Some problems actually do exist in the real world, and if we fail to detect them, some children will be denied services that could be helpful to them, and preventive efforts in general will be seriously undermined.

Can Clients Provide Valuable Feedback to Clinicians About Their Personality Interpretations? A Reply to Greene

C. R. Snyder, Mitchell M. Handelsman, and Janet R. Endelman
University of Kansas

Greene's article on the Barnum effect is criticized on conceptual, methodological, and statistical grounds. A reanalysis of the data is presented, along with background research that conflicts with Greene's conclusions regarding (a) the ability of people to judge the accuracy of personality interpretations that they receive and (b) the role of feedback uniqueness in that judgment.

In commenting on previous Barnum effect research, Greene (1977) suggested that the recipient of personality feedback "accepts an interpretation as being descriptive if it is accurate, regardless of its uniqueness" (1965, emphasis added). Contrary to this assertion, however, previous studies have indicated that the uniqueness of feedback does influence acceptance on two levels. First, a consistent finding is that the higher the base-rate accuracy for people in general (i.e., the lower the uniqueness), the greater the acceptance of the feedback (e.g., Collins, Dmitruk, & Ranney, 1977; Merrens & Richards, 1970; Mosher, 1965; O'Dell, 1972; Snyder & Shenkel, 1976; Sundberg, 1955; Weisberg, 1970). That is, the content of the interpretive feedback should not be unique in order to elicit acceptance on the part of the recipient. Second, it is important for the recipient of diagnostic feedback to believe that the feedback is derived specifically for him or her (i.e., that it is unique). Research on this point has shown that recipients of feedback are more acceptant of the feedback when they believe that it was "specifically derived for them" on the basis of psychological tests, as compared to "statements that are generally true of people" (Snyder, 1974; Snyder, Larsen, & Bloom, 1976; Snyder & Larson, 1972; Snyder & Shenkel, 1976; Ziv & Nevenhaus, 1972).

Other comments are warranted on the methodology used in the Greene (1977) study.

Greene used a fairly typical procedure in the Barnum effect paradigm (cf. Snyder, Shenkel, & Lowery, 1977, for review). Undergraduate students in two classes completed a psychological test in one class session, and in the next class session each student was given the same interpretive feedback. Students then rated the interpretation

according to the extent to which this personality interpretation described their own personality. Second, they rated the extent to which it described them as a unique individual, that is, as different from their classmates. Third, they rated the extent to which it described one of their classmates. (Greene, 1977, p. 965)

Subjects responded to each question on a 5-point scale (5 = excellent, 4 = good, 3 = average, 2 = poor, 1 = very poor). Methodologically, the within-subject sequence may have sensitized subjects to become highly skeptical. It would have been more desirable to counterbalance the order of items to handle this possibility. Also, it should be noted that any within-subject differences may be due in part to shifting internal anchor points resulting from different content across questions.

Given the aforementioned design, a Class (senior vs. junior-sophomore) \times Questions (1, 2, 3) analysis of variance would have been preferable to the single one-way analysis of variance that was reported. (In this subsequent analysis the reader should be cautioned not to overinterpret the results because of the previously mentioned problems with the three questions.) When Greene's (1977) data were reanalyzed this way, the main effects of class and questions were significant. The main effects were qualified by a significant Class \times Questions interaction, $F(2, 98) = 3.22, p < .05$. This inter-

The authors gratefully acknowledge the assistance of Roger Greene in providing the data of his study for further analysis.

Requests for reprints should be sent to C. R. Snyder, Graduate Training Program in Clinical Psychology, Fraser Hall, University of Kansas, Lawrence, Kansas 66045.

action resulted because the senior and junior-sophomore classes did not differ significantly on the "describe classmates" question, but the junior-sophomore class (a) accepted the interpretation more highly, $t(49) = 2.06$, $p < .045$, and (b) perceived the interpretation as being more unique for them than did the senior class, $t(49) = 2.90$, $p < .006$. Whether these differences between classes are due to greater sophistication on the part of the senior as compared to junior-sophomore class members, as Greene (1977) suggested, is not discernable from these data. This follows because the two classes may have differed on a multitude of possible dimensions that may influence their reactions to feedback (e.g., time of course in terms of day and semester, course content, instructor, or class composition in terms of sex, age, race, etc.). Also the inference made by Greene (1977) that students could realize "that the same interpretation could as accurately be applied to *any* of their classmates" (Greene, 1977, pp. 965-966, emphasis added) is overstating the results, since the actual statement read "rate the extent to which it describes *one* of your classmates." One other suggestion regarding the present procedure is that performing the experiment in a classroom setting may have aroused far more suspicion on the part of subjects than the individual testing and feedback situation that is typical of actual clinical practice and recent research within this paradigm. The literature suggests that the situation in which a client receives interpretive feedback from a clinician may yield a rather highly acceptant and undiscerning recipient of feedback (Snyder & Clair, 1977).

Greene's conclusion that "the Barnum effect can become a less formidable adversary if the clinician is careful to instruct the student or client as to exactly what questions are to be answered" (Greene, 1977, p. 966) is unwarranted given the previous mentioned methodological limitations. Additionally, although clinicians in actual practice may ask clients to give their acceptance reactions to feedback, they probably do not ask clients about the uniqueness of the feedback. Finally, it is unfortunate that the previous Barnum effect literature does not support Greene's other important conclusion, that "the student or client can be a source of valuable feedback to the clinician in honing his or her clinical skills" (Greene, 1977, p. 966). It has been found that students cannot distinguish bona fide personality interpretations from randomly generated or bogus interpretations (Dies, 1972; Sundberg, 1955). In fact, several studies even found that the generalized inter-

pretations are seen as more accurate than bona fide ones (Merrens & Richards, 1970; O'Dell, 1972).

An old quote comes to mind in regard to this entire issue. Upon hearing of his death, Mark Twain wrote the following cable to the Associated Press in 1897, "The reports of my death are greatly exaggerated" (cited in Bartlett, 1968, p. 763). Given the present state of research, the same could be said of the Barnum effect.

Can Clients Provide Valuable Feedback to Clinicians About Their Personality Interpretations? Greene Replies

Roger L. Greene
Texas Tech University

Snyder, Handelsman, and Endelman's response to Greene overlooked several significant issues that are important in reconceptualizing research on students' acceptance of generalized personality interpretations. These issues are stated explicitly, and their relevance to research in this area is described.

Snyder, Handelsman, and Endelman (1978) have provided an interesting commentary on Greene's (1977) article on student acceptance of generalized personality interpretations. Somehow they have managed to overlook the major thesis of his article, and instead they have chosen to comment on several tangential issues. Since they overlooked the major point of his article, it will be reiterated here so that other researchers will not make the same oversight. Generalized personality statements are constructed so that these statements are an *accurate* (true) description of all students. Hence, it does not make sense then to ask students whether these statements are accurate when in fact they are constructed to be so. Unfortunately, most previous research on students' acceptance of generalized personality interpretations has asked the student how accurately such statements fit his/her personality (e.g., Forer, 1949; Snyder, 1974; Ulrich, Stachnik, & Stainton, 1963). The issue of importance is whether students believe these generalized personality interpretations to be unique.

Since Snyder et al. (1978) use the term *uniqueness* in two different senses, it is not clear exactly what point they are trying to make in their comment on this issue. Uniqueness can be used to describe the base-rate accuracy of a generalized statement (i.e., the lower the base-rate accuracy of any statement or group of statements, the more unique the statement

would be). Uniqueness is also used to describe the procedures whereby the student is led to *believe* that the particular generalized statements that he/she receives have resulted from the interpretation of some type of assessment process. The appropriateness and effectiveness of the procedure used by the researcher to create this illusion of uniqueness of test interpretations no doubt will affect students' ratings of generalized interpretations, as Snyder et al. indicate. However, this procedure can be and should be independent of the question whether the set of generalized interpretations that the student receives is unique or descriptive of only one person. Greene (1977) used the word *unique* in the latter sense, in that he asked students whether they realized that generalized personality statements could be applied as appropriately to one of their classmates as to themselves. Snyder et al. (1978) stated that "the *content* of the interpretive feedback *should not* be unique in order to elicit acceptance on the part of the recipient" (p. 1493). Why they should want to explicitly eliminate the only pertinent question that can be asked of generalized personality interpretations is not clear. To reiterate an earlier point, it makes little sense to ask students whether generalized interpretations are accurate. The imperative question is whether students can recognize that generalized interpretations are trivial because they can be applied to anyone, and Greene (1977) demonstrated that students can indeed recognize the triviality of generalized statements at least in one context.

The author appreciates the comments of James R. Clopton and Donald H. Baucom on a preliminary draft of this manuscript and the literary contribution of Robert H. Weiner.

Snyder et al. (1978) do raise one valid methodological issue. Since a repeated-measures design was used in Greene's (1977) original study, it is necessary to conduct a similar study using either a between-subjects design or a counter-balanced repeated-measures design to determine the generality of his results. Only empirical data

can answer the methodological question that they have raised.

One final issue remains to be discussed—whether clients can provide clinicians with feedback about their personality interpretations. Snyder et al. (1978) stated that “although clinicians in actual practice may ask clients to give their acceptance reactions to feedback, they probably do not ask clients about the uniqueness of the feedback” (p. 1494). Clinicians who are interested in avoiding the pervasive influence of the Barnum effect should be specifically asking their clients the latter question. If clients can recognize whether personality interpretations are unique, which needs to be empirically tested, clients can be a valuable source of feedback to clinicians.

In concluding this reply, a quote comes to mind: “What’s gone and what’s past help/Should be past grief.” (Shakespeare, 1963, p. 65: *The Winter’s Tale*, Act III, Scene 2). Hopefully, experimenters will allow the previous approach to studying students’ acceptance of generalized personality interpretations to die a peaceful death and instead infuse some new direction into an interesting research area.

Premature Conclusions Regarding Black and White Suicide Attempters: A Reply to Steele

Richard C. Bedrosian and Aaron T. Beck

Department of Psychiatry
University of Pennsylvania

The conclusion reached by Steele, that his samples of black and white suicide attempters were clinically similar is questioned, as is his inference that his results require a reexamination of the supposed need for separate black and white psychologies. Specific criticisms are raised regarding some of the variables chosen by Steele for his comparisons, and the manner in which he chose to interpret his data.

As a result of his comparison of black and white suicide attempters, Steele (1977) concluded not only that the two groups were clinically quite similar but also that his data necessitated a reexamination of the contention that separate psychologies are needed for blacks and whites (Mosby, 1972). Although data contrary to the latter conclusion (which is viewed by us as premature) will no doubt be drawn from a variety of sources by other critics, the point to be made herein is that the proclamation of "no difference" between the black and white suicide attempters in Steele's sample was likewise ill-advised.

Steele concluded that the black-white differences in his sample were negligible after having observed in his comparison between the two groups that "only 11 out of the 42 clinical variables are statistically significant at the 5% level of confidence" (Steele, 1977, p. 983). Implicit in his statement is the assumption that on an *a priori* basis, many more of the variables should have revealed a difference between the two groups. In other words, Steele seems to have assumed that all or most of the variables that he examined represent equally important aspects of suicidal behavior and/or ideation, and that the way to test for differences between the two groups is to compare them on a host of variables and then assign a "box score." Apparently no effort was expended to select suicidal risk variables that reflect either observed or hypothesized differences between white and black subcultures.

What the box score approach also overlooks, of course, is that some variables may be more useful or interesting than others. With regard to suicidal behavior, "pessimism and hopelessness" might be more relevant as a predictor than "paranoid delusions" or "patient's acknowledged attempt to get some sleep," for example.

Closer examination of the indices used by Steele (1977) reveal some variables that might have been expected to bear little relation to the phenomenon of suicidal behavior. "Depressive delusions," "paranoid delusions," and "thought disorder" all presumably referred to the presence of psychotic processes on the part of the suicide attempter. Yet there is evidence that the neurotic-psychotic distinction may not be particularly relevant to the study of suicidal behavior. In a study of attempters, neurotics and psychotics showed no differences on self-report and clinical measures of suicidal intent, as well as on ratings of the lethality of their attempts (Lester & Beck, 1976). On the other hand, in view of the data supporting a relationship between alcohol intake and suicidal behavior (Mayfield & Montgomery, 1972), Steele might well have included a measure of alcohol consumption at the time of the attempt. These examples were not raised in order to second guess Steele; they have been included here in order to caution against premature closure on the issue of the black-white comparison.

If one assumes as Steele (1977) apparently does not that his data represent random results, then his findings do have some clinical relevance. Whites scored higher than blacks on ratings of depression and hopelessness, two variables that traditionally have been used to assess suicidal intent and that have consistently surfaced in the

Requests for reprints should be sent to Richard C. Bedrosian, Department of Psychiatry, Room 602, University of Pennsylvania, 133 South 36th Street, Philadelphia, Pennsylvania 19104.

literature as predictors of suicidal risk (Beck, Kovacs, & Weissman, 1975; Minkoff, Bergman, Beck & Beck, 1973). Moreover, Steele reported that blacks were less motivated to appeal for help and that they spent less time between planning the act and actually making the suicidal attempt. In trying to assess the suicidal risk in a black patient, the psychotherapist may find that the usual cues (e.g., hopelessness, depression, "cry for help") for making such judgments are less useful than if a white patient had been involved. Further, Steele's data suggest that the black patient may require a more rapid intervention in order to avoid an attempt once the suicidal ideation has been detected.

A more adequate test of whether black and white suicide attempters represent different populations should use dependent variables that are (a) known to bear a relationship to the phenomena of suicidal behavior and/or ideation and are (b) presumed to reflect some area of dissimilarity, either observed or hypothesized, between black and white subcultures. This critique raised questions about the way in which Steele (1977) satisfied the first criterion, but it seems clear that he paid no attention to the second. Some well-informed hunches about where the differ-

ences between black and white suicide attempters might lie could have provided Steele's project with a clearer focus, and perhaps, greater credibility.

Steele's Reply to Bedrosian and Beck

Robert E. Steele
University of Maryland

The two basic criticisms of Bedrosian and Beck are addressed: the appropriateness of the variables chosen and the interpretation of the results with regard to black psychology. A rationale is given for the inclusion of clinical variables that were not particularly relevant to suicide attempt behavior. Two additional variables, history of alcohol and illicit drug abuse, are reported to support the similarity position between black and white suicide attempters. A final comment is made on the relevance of the need for a separate black psychology.

Bedrosian and Beck's (1978) criticism of my recent article (Steele, 1977) revolves around two issues—(a) the appropriateness of the variables chosen to examine black-white differences in suicide attempt behavior and (b) the prematurity of my claim that one empirical "box score" study is sufficient to question the viability of a black psychology. Bedrosian and Beck chose to address the first point themselves and suggested that "other critics" would attack the latter. Let me take this opportunity to counter both Bedrosian and Beck as well as to address the other critics on the second issue.

Bedrosian and Beck's (1978) first line of attack was that I assume that "all or most of the variables . . . represent equally important aspects of suicidal behavior and/or ideation" (p. 1498). I made no such assumption. In fact, the data summarized and condensed in the first paragraph of Footnote 1 (Steele, 1977, p. 984) were initially presented in three tables in the original manuscript submitted to this journal. These variables were selected after an extensive literature review of suicide attempt behavior. Key variables identified by Farberow and Schneidman (1961) and Stengel (1964) were included in this study.

The rationale for including the other "host of variables" was that in addition to focusing on suicide attempt behavior between blacks and whites, I wanted to see what an extended "clinical profile" between these two groups would look like in light of the claims made by *others* that there is a need for a separate black

psychology. This claim does not represent my point of view. Therefore, Bedrosian and Beck are incorrect to suggest that I expected "on a priori basis" black-white differences.

Bedrosian and Beck's (1978) second line of attack was my inappropriate inclusion of psychotic clinical variables (depressive delusions, paranoid delusion, and thought disorder) in light of the findings by Lester and Beck (1976). I would like to point out to my critics that my study was planned, the literature review was conducted in 1969, and the results of the Lester and Beck study were reported in 1976.

Bedrosian and Beck's third line of attack was that I committed the "sin" of omission; that is, I left out a key variable known to be related to suicide attempt behavior, namely alcohol consumption. I concede that my study would have been improved if this variable had been included. Let me hasten to add, however, that the residents did take a history of alcohol and illicit drug abuse as a part of their medical work-up. On these two variables, which were not reported in the original study, there were no statistically significant differences between black and white suicide attempters that are consistent with my interpretation that there are no meaningful "clinical" differences between these two groups.

Let me make a final comment on the second point that other critics will address. It was not my original intention to suggest that this one study is sufficient to invalidate the claim that a black psychology is needed. However, my interpretation of these results does not provide supportive evidence for a black psychology notion. I feel that my call for a reexamination of the need for a black psychology in light of empirical evidence is a valid one. A recent study

by Steele (1978) that examined psychosocial factors in depression (a variable related to suicidal behavior) found that there were no significant relationships between race and measures of depression. Race did interact significantly with other factors such as social mobility. Upwardly mobile blacks and downwardly mobile whites showed more psychological disturbances on factors relating to depression. It is my growing conviction, which has some empirical support, that race and/or ethnic identity is a critical factor in determining behavior in complex interactions with other significant variables such as sex, religion, social class, physiological correlates, and so forth. Just because each of these factors may be important, I do not feel that it makes theoretical and/or empirical sense to elevate any of these factors to a salient status, such as a "female" and/or "black" psychology. I agree with Kluckhohn (1949) that human beings regardless of our cultural backgrounds share certain universal characteristics, that certain characteristics are shared with other members of our ethnic groups, and that we share certain characteristics as individuals. It is the goal of psychology to understand the complex interrelationships among these three factors. I

do not feel that a narrowly conceived ethnic and/or individual psychology will achieve this goal.

Psychotherapy or Massage Parlor Technology? Comments on the Zeiss, Rosen, and Zeiss Treatment Procedure

Kent G. Bailey
Virginia Commonwealth University

There are numerous ethical, moral, philosophical, and social psychological issues involved in modern sex therapy. Psychologists have accorded sex therapy a warm reception into the field, but present ethical guidelines are insufficient to protect clients from psychological damage in the form of massive intrusions on privacy and reoriented moral and religious values. Further, the more explicit procedures seem to carry a message to society that "anything goes." The Zeiss, Rosen, and Zeiss procedure is used as a reference point for discussing these various issues.

In a recent review, Byrne (1977) outlined the progressive evolution of research on sexual behavior from animal studies in the early phases, to primitive cultures, abnormal sexuality, and finally up to the contemporary focus on normality emanating from Freud, Kinsey, and Masters and Johnson. Byrne stated that social psychologists were attracted to the area by virtue of revolutionary societal changes in attitudes and actual behavior, by research initiated by the Commission on Obscenity and Pornography, and by the pressing need to solve the problem of unwanted conception. Following his in-depth historical analysis of research on sexuality, Byrne concluded that social psychologists have much to gain and much to offer by providing a "warm welcome" to this fundamental area of social psychological interest.

Perusal of recent issues of the *Journal of Consulting and Clinical Psychology (JCCP)* reveals that sex research is being warmly received by clinical researchers and therapists as well, and, further, it appears that there is a parallel trend to use increasingly explicit materials, methods, and procedures in the sex laboratory. A recent *JCCP* issue, for example, included a study in which introductory psychology students viewed films of masturbation and subsequently responded to various measures of sexual arousal and affectivity (Mosher & Abramson, 1977), and another study used a behaviorally oriented masturbation procedure for treating inorgastic women

(Zeiss, Rosen, & Zeiss, 1977). Although both of these studies produced some data of interest, the explicit, high-impact treatment procedures raise numerous ethical, moral, philosophical, and potential legal issues that were not addressed, and the crucial issue of cost versus benefit was virtually ignored. In other words, there was little concern as to whether the data or treatment effects generated outweighed the potential psychological harm to the subject or client, and, more importantly, there was little concern regarding the cumulative social impact of the "anything goes" message that such procedures communicate to the subject, the client, other professionals within and out of the field of psychology, and, finally, at some point, to the public at large.

Using the Zeiss et al. (1977) study as a reference point, I would like to address some of the general issues raised above in greater detail.

The Ethical Issue

Although intangibles like "intent," "competence," and even "confidentiality" possess unclear ethical boundaries, all therapists agree on one thing—Sexual liaison between therapist and client is unethical and is to be uniformly proscribed (American Psychiatric Association, 1973; American Psychological Association, 1977). Furthermore, such contact produces negative psychological effects on the client in most instances (Taylor & Wagner, 1976) and typically represents a form of exploitation of female clients by male therapists (American Psychological Association, 1975). Indeed, sexual contact within the therapy relationship may be seen as

Requests for reprints should be sent to Kent G. Bailey, Department of Psychology, Virginia Commonwealth University, Richmond, Virginia 23284.

tantamount to breaking the incest taboo (Taylor & Wagner, 1976), for like it or not our desperate, anxious, and lonely clients cast us in a parental role, and our own needs catalyze the process.

Now, we have here an instance in which a particular form of sexual expression is condemned as morally reprehensible, contrary to client welfare, and patently unethical. It is rare that behavioral scientists are so definitive about anything, and I cannot think of any other instance in the sexual realm in which the blue pencil applies with such stringency. Given the innumerable possibilities for sexual behavior and misbehavior, it is surprising that only therapist-client sexual contact should warrant our ire. I suggest that we be fair, and, rather than "warmly welcoming" any new combination or permutation of arms, legs, and genitalia that leads to orgasm, we should use caution and discretion in intruding into the sex lives of our clientele.

Unfortunately, the Zeiss et al. (1977) study fails to exercise such caution and discretion, and what we have instead is a simplistic, functionalistic, treatment "program" that successfully yields orgasm, ignoring all the while the more profound psychological implications of the procedure. I in no way question the intent or motivation of Zeiss et al., for they behaved as ethical behavior therapists should, by using the simplest, most direct, and most effective techniques to achieve treatment goals in the shortest time possible (AABT, 1976). I do, however, question their methods and a system of professional ethics (or lack thereof) that allows therapists to declare open season on the sexually maladjusted client, with the only interdiction being that the therapist cannot join in on the fun. If sexual liaison with the client is the therapist's version of "playing house," then no-holds-barred treatment procedures like those of Zeiss et al. makes for "playing doctor," with the willing, dolllike client going along with anything—and I mean anything! The gradual fading in of Mr. A comes to mind here (Zeiss et al., 1977, p. 893), along with Mrs. A apparently thrusting and vibrating herself into a case of pneumonia, or, better still, Mrs. B's sudden, mysterious sexual longing for organic vegetables following her reading of Friday's (1974) *My Secret Garden*.

All of this would be humorous were it not so tragic. It is a mystery to me how conversational psychotherapy has made the sudden transition to massage parlor technology involving vibrators, mirrors, surrogates, and now even carrots and cucumbers! Can we say that the empirical, theoretical, and philosophical groundwork has been

laid for such procedures? Do we have data on the psychological, social, and spiritual side effects of such procedures? I think not; it is more parsimonious to assume that therapists are giving clients what they want (or think they want) whether they need it or not. Furthermore, the distinction between "legitimate" and "illegitimate" sex therapists is becoming increasingly blurred as the money pours in and the pop therapy bandwagon rolls on. The Zeiss et al. procedure represents one of the more dramatic instances of "legitimacy by acclamation," with applause supplied by the behavioral community on the one hand and the instant gratification crowd on the other. The Zeiss et al. procedure and others like it do little to allay Albee's (1977) fear that modern society is creating "an impulse-indulgent society of consumers, and psychotherapists have become the new gurus explaining life's elusive purpose" (p. 150).

Our system of professional ethics, then, should develop the breadth and depth to accommodate more than the obvious parameters of competence, confidentiality, interpersonal relations, use of tests, effectiveness of treatment, and so forth. It should also grapple with the subtler aspects of client welfare, including intrusions of privacy, indirect assaults on the client's moral and religious values, and, most importantly, abuse of the power to direct and facilitate social change. Just as Freud, Skinner, and even Spock have effected massive social change directly with new ideas and techniques, and indirectly with innumerable covert stipulations that emanate from their work, the modern sex therapist carries a powerful message to a credulous public looking to psychology for guidance. Although the field of psychology in general implicitly espouses exaggerated individualism (Hogan, 1975), liberal ideology (Ornstein, 1975), and instant gratification (Albee, 1977), it is the sex therapist who most seriously assaults the traditional institutions (see Campbell, 1975) of marriage, family, and religious values. It is time that we come to grips with these admittedly elusive side effects to therapy, and it is time that we set proper ethical guidelines and sanctions within the field before inevitable legal and professional disasters befall us from without. The recent brouhaha at the State University of New York at Albany (Smith, 1977) is a frightening illustration of the catastrophes that can befall the psychologist when ethical guidelines are ignored or are given mere token consideration.

The Legal Issue

As Tryon (1976) pointed out, concern with the ethics and legality of behavioral practices increases in proportion to the effectiveness of learning principles applied to human behavior. When the therapeutic procedures are highly specific and highly effective, the independent variables are laid bare for legal scrutiny, and this naturally leads to discussion of the whos, whens, and wheres of using such powerful procedures. The Zeiss et al. (1977) procedure ranks at the top in both specificity and "effectiveness" in the orgasmic sense, and the question arises as to how such procedures would fare in the courtroom.

Tryon (1976) reminds us that we live in an increasingly litigious society, and behaviorally oriented clinicians especially need to take necessary defensive precautions in order to avoid malpractice suits. The most important defensive precautions revolve around the subtleties of informed consent and several steps are involved: (a) The therapist lists behavioral goals requested by the client; (b) the therapist provides a statement of goals, which may or may not parallel those of the client; (c) once client and therapist goals are reconciled, the therapist makes full disclosure of treatment options, and procedures are described in detail; and finally, (d) the therapist acknowledges any reasonable *side effects* that may be expected as a result of treatment. In reading the Zeiss et al. article, I cannot tell whether any of the above precautions were taken, but I presume, as good behavioral therapists, that the authors went so far as to reconcile client and therapist goals, and hopefully the clients were presented with treatment alternatives and contingencies. However, the authors appear totally insensitive to the serious matter of side effects, and concern is instead focused on technical considerations and criteria for patient selection and rejection.

It is debatable as to whether the Zeiss et al. procedure would survive a malpractice suit by virtue of failure to fully consider potential side effects. For example, Mr. and Mrs. A were appropriately cooperative and seemed to enjoy their rather bizarre six-step program as it was in progress, but imagine what could happen a year later when Mr. A looks back and sees himself and his wife as "demeaned," "humiliated," and suffering "irreparable psychological harm" by virtue of the massive reorientation of habits, values, and self- and other-percepts that followed from treatment. Could the Zeiss et al. procedure withstand rhetorical assault from counsel for the plaintiff, who would, no doubt, dwell

on the grievous "wounding of spirit" suffered by his or her clients?

The client's right to privacy is another important issue with potential legal implications. Until sex therapy came along, the psychotherapist merely intruded into every cognitive crack and crevice possible, but now we "play doctor" to the fullest and perform behavioral "operations" that intrude into the client's private life to a degree unimaginable a decade ago. Unless the sex therapist can demonstrate that less intrusive alternate procedures are not feasible on a cost-benefit basis, then it seems to me that he or she could be subject to a malpractice suit if challenged by a client on that basis. I am unaware of any empirical research that has addressed the question of differential effectiveness vis-à-vis "hard" sex therapy procedures like those of Zeiss et al. versus "soft" conversational or less direct approaches. Unless, the hard, more intrusive approaches are found to be vastly superior in effectiveness to softer ones, then application of the former approaches would be at worst unethical and possibly illegal, and at best, just bad therapy.

The Power Issue

One of the most important and generally ignored variables in the therapy situation is that of therapist power and dominance over the client. Anyone who has supervised therapy practicum for a 2nd or 3rd-year clinical student, however, is immediately struck with the jockeying for control that goes on between this young pre-PhD and the client, and when we are informed that "rapport has been established," we know, at long last, that the neophyte therapist has finally gotten the upper hand. Were it not for the almost hypnotic power of the therapist, one wonders whether therapy would occur at all, for a great amount of what we call therapy is just plain persuasion and the selling of agendas of various sorts. It is difficult to imagine therapy proceeding on the basis of client aversion and disrespect for the therapist, and it seems to me that client cooperation is the most precious commodity in the therapy situation.

With such a gross status asymmetry and imbalanced dominance relationship, the therapist is in a position to extract levels of "obedience" that Milgram could only dream of, and such power necessarily requires judicious control and self-monitoring throughout the entire therapy process. In view of these considerations, I am not surprised that Zeiss et al. (1977) had little

difficulty in introducing the dildo in treatment, nor would I disagree that "clients will accept the procedures [the six-step program] when they are presented with an appropriate rationale" (p. 894). It might be more instructive to ask, "What will a client who needs therapy *not* do for the marketer of the product that he or she wishes to consume?" The answer—practically nothing! If anyone doubts this assertion, I suggest that they read Rosen's (1977) article dealing with the ready tendency for clients to sign away their rights to privacy under sign-away pressure, one type of which is the implicit message "do it my way or you don't get therapy." Thus, we see that mere client consent, or client capitulation as the case may be, is a suspect criterion for legitimizing a particular therapeutic intervention.

There is a related issue that I wish to bring up at this point. Despite intellectual acceptance of the trappings and regalia of the sex laboratory, I see little evidence that sex therapists wish to ply their trade on members of their own families, friends, neighbors, or loved ones. Rather, it is the impersonal stranger who is the modal consumer of the sex therapists' goods, and, as such, may be treated within the context of a dangerous underlying double standard. According to W. D. Hamilton's kinship selection theory (Barash, 1977), we tend to be more altruistic and beneficent toward those with whom we share the greatest number of genes, whereas those who share few genes with us fall in the despised, or, at best, tolerated outgroup. At the social level, we see a similar in-group versus out-group theme in Nietzsche's master morality and slave morality, a double-standard in which the aristocratic class exploits and oppresses the masses for their own good. Perhaps comparing Hamilton's theory to the therapy relationship is a false analogy, and perhaps suggesting that therapists can, in some respects, be seen as an aristocratic class ministering to the masses is a bit strong, but there is little evidence to suggest that clients are treated with the dignity and respect that we reserve for ourselves and significant others. For example, I have often seen therapists speak very cavalierly of "divorce," "masturbation," "surrogate partners," and the like in reference to clients while their own divorces and sex lives are treated with the utmost reverence. I personally believe that clients deserve the respect and reverence that we accord our loved ones, and I question whether the Zeiss et al. procedure, and similar ones, operate on that basis.

The Philosophical-Theological Issue

I believe that sex therapy is appropriate and desirable when performed by a *psychotherapist* who combines sensitivity to philosophical, moral, and theological issues with his or her armamentarium of technological skills. Without this sensitivity, poking and punching with dildos and the like becomes little more than animal husbandry at the human level. When science discards its humanity for the sake of technology, its subjects and clients become things rather than people (Goodfield, 1977), and science becomes estranged from the society that sustains it. As Goodfield so eloquently reminds us, this is nothing new, for science has, from its very beginning, been alienated from both the arts and the laity. She summarizes the historical background for the two most recurring criticisms of science: (a) First, science is cold and inhuman and does not concern itself with the needs of society; and (b) second, somehow science manages to extract the warmth and beauty of the world, and, in the process, drains itself. In concluding her essay, Goodfield asserted that science and society can no longer afford estrangement, and the scientist must work to understand the public as well as vice versa. Furthermore, the complexities of modern society disallow professional allegiance to a methodological ethic alone; rather, the scientist must work to apply "knowledge of facts in new compassionate ways" (Goodfield, 1977, p. 585).

One good way to start is by recognizing that a plurality of perspectives is needed to gain even minimal understanding of something so apparently straightforward as the masturbatory behavior of a given client. It is naive and arrogant to assume that masturbation can be instituted or facilitated in a treatment program without due consideration of the impact this may have on the moral and spiritual well-being of the client. Campbell (1975) has argued against psychotherapy's unwarranted rejection of moral tradition, and, more recently, the issue of therapeutic intrusion into the realm of religious belief has surfaced with considerable pandemonium (Cohen, 1977; McLemore & Court, 1977; Stokes, 1977). Such discussion is long overdue, and as McLemore and Court (1977) put it, "it would be professionally irresponsible of psychologists to ignore the wider implications of deciding to alter clients' belief systems" (p. 1175). Zeiss et al. may argue that none of this applies to their procedure, but knowledgeable behavior therapists (e.g., Lazarus, Mahoney, Meichenbaum) have conceded that the cognitive sphere cannot be

artificially separated from action and behavior. On the face of it, a masturbation program of any type would appear to carry innumerable hidden messages and covert stipulations—all or most of which are antithetical to Judeo-Christian traditions—and it is high time that sex therapists pay some attention to the impact that their procedures have on clients' values and religious beliefs.

Concluding Comment

As Kuhn (1970) tells us, science in its advanced stages is naturally insulated from society and social problems, and each more-or-less isolated scientific group shares common values and beliefs, and a restricted view of the world is taken for granted. It is only within such a context that the more explicit forms of sex therapy operate, hidden behind behavioristic jargon and academic degrees. Only on closer scrutiny by the disciplinary nonbeliever or the lay outsider do we see that distinctions between legitimate and illegitimate forms of sex therapy are extremely difficult to make; and only then do we see the tenuous ethical, moral, and professional nature of the enterprise.

Is Masturbation Still Wrong? Comments on Bailey's Comments

Nathaniel N. Wagner
University of Washington

Although Bailey in commenting on the Zeiss, Rosen, and Zeiss article on masturbatory techniques in sex therapy, sees ethical, moral, philosophical, social and psychological issues, he lists no specific negatives except "potential side effects." Bailey demands that therapy using directed masturbation must be "vastly superior" to conventional techniques or else it is unethical. No rationale for this discrimination is presented except potential side effects. The antiscientific nature of this argument is noted.

Bailey's (1978) comments on the Zeiss, Rosen, and Zeiss (1977) article on "Orgasm During Intercourse: A Treatment Strategy for Women" continues a long tradition of intellectual and emotional arguments against masturbation. This tradition reached its zenith in the mid-18th century when S. Tissot of France wrote "Onana, a Treatise on the Diseases Produced by Onanism" (Dearborn, 1966). Following the intellectual and moral position set forth by Tissot in 1866, a British physician, Isaac Baker Brown, described the surgical removal of the clitoris to prevent masturbation and its serious side effects. The title of his volume communicates the flavor: "On the Curability of Certain Forms of Insanity, Epilepsy, Catalepsy and Hysteria in Females" (Corea, 1977).

The essence of Bailey's (1978) criticism of Zeiss et al. is that they are insensitive to the "psychological, social, and spiritual side effects of such procedures" (p. 1503). A little later, Bailey acknowledges that "these admittedly elusive side effects to therapy" (p. 1503) have not occurred as yet. This does not prohibit Bailey from warning of the serious negatives that may accrue to "the traditional institutions of marriage, family, and religious values" (p. 1503).

Let us be clear about what Zeiss et al. (1977) recommend in their article. A six-step treatment program for women who are inorgasmic during intercourse is described. The program helps these women experience orgasm with vaginal containment of their partner's penis, whereas

previously they could only experience orgasm with manual stimulation of the clitoris. Masturbation with a dildo is used as a means of generalizing the response from clitoral stimulation to vaginal containment. There is a thoughtful discussion of the work of Masters and Johnson (1966) demonstrating the physiologic similarity of orgasm regardless of the main source of stimulation. Zeiss et al. (1977) argue that if a woman wants to experience orgasm with intercourse, this "is a justifiable behavioral goal" (p. 891). Although controversial among sex therapists, their position is a reasonable one that has many adherents. The opposing view is that all orgasms are equivalent and that it is a waste of time and may be unsuccessful to attempt to change the orgasmic pattern.

That many women seek medical and psychological assistance with orgasmic problems is well established. Masters and Johnson (1970), LoPiccolo and Lobitz (1972), Kaplan (1974), Barbach (1974), and Heiman, LoPiccolo, and LoPiccolo (1976) provide clear evidence of continued innovation, treatment, and research into this aspect of female sexual dysfunction.

Bailey's (1978) critique suggests a return to more conventional talking therapy as less dangerous of potentially serious side effects. He talks about the harm that can befall therapists if they do not use "caution and discretion in intruding into the sex lives of our clientele" (p. 1503). It is hard to understand how one can intrude into the sex life of someone who comes for assistance with a sexual problem.

In an interesting turn for one who argues from an ethical and moral stance, Bailey (1978) criticizes sex therapists for not using these techniques on "their own families, friends, neighbors, or loved ones" (p. 1505). Apparently, the

need for the therapist to be as objective as possible eludes him. It is an elementary fact of therapeutic practice, as medicine has long acknowledged, that it is foolish and dangerous to be professionally involved with persons with whom one has a preexisting emotional bond.

The Story of Onan

When the arguments that Bailey raises are carefully examined, it is clear that masturbation, and its presumed serious side effects, is the central issue. It may be helpful to examine the historical origin of our attitudes toward masturbation. Within the western tradition, the Old Testament Biblical story of Onan (Genesis, 38, 6) is central. Onan refused to impregnate his older brother's widow, practicing coitus interruptus instead, which brought the wrath of God and Onan's death. The biblical scholars' argument as to whether Onan's sin was in refusing to obey the levirate requirement to give seed to his brother or whether it was in the spilling of his seed on the ground is not at issue here (Bullough, 1976). The word *onanism* has historically been synonymous with masturbation (Freud, 1927), and it is currently the word for masturbation in German and other European languages. Clearly, Onan's spilling of the seed on the ground soon evolved to other forms of spilling seed on the ground, that is, masturbation. The masculine bias should be noted.

Within the confines of a propopulation stance, which was rational and justifiable in Biblical times, masturbation threatened the survival of the species. High infant mortality and an overall high death rate helped to develop a pronatalist policy of severely censuring any nonreproductive sexual behavior (i.e., masturbation, homosexuality, and oral sex). This is the context in which Bailey (1978) seeks to "protect clients from psychological damage in the form of massive intrusions on privacy and reoriented moral and religious values" (p. 1505).

It is interesting that on January 22, 1976, Pope Paul VI reasserted the unequivocal opposition of the Roman Catholic Church to masturbation: "The moral sense of the faithful have declared without hesitation that masturbation is an intrinsically and seriously disordered act" (Kosnik, 1977, p. 306). Religious thought, however, is not uniform in its condemnation of masturbation and other nonreproductive acts. There is a growing sense of the need to reexamine traditional views (The United Church of Christ, 1977).

From a point of view that sees overpopulation as the Number 1 problem of the world

(Hardin, 1968), one could argue that masturbation is a constructive way of dealing with sexual interest. To continue to perceive masturbation as intrinsically psychologically damaging is archaic and simply not true. If there are serious side effects, where is the scientific literature documenting these effects? Bailey has not made the case.

The Ethical Issue

Having responded in a general way to the highly emotionally charged criticisms of Bailey, I would like to respond specifically to each issue raised. The first is the ethical one. Bailey (1978) states that Zeiss et al. are allowed "to declare open season on the sexually maladjusted client, with the only interdiction being that the therapist cannot join in on the fun" (p. 1503). The fact that all therapies include value judgments is not new and has been thoughtfully discussed by London (1964). Behavioral therapists are probably less guilty of making value judgments in the guise of therapy than such nonbehavioral therapists as psychoanalysts or Gestalt or humanistic therapists. A thoughtful discussion of the ethical problems in behavior therapy is provided by Goldfried and Davison (1976). Zeiss et al. are not any more unethical in using masturbation as a therapeutic technique than scores of talking therapists who have used their client's masturbatory fantasies in therapy. Zeiss et al. are probably even more effective in helping the client reach the goal that brought the person into treatment.

The Legal Issue

Bailey's (1978) argument here is that the techniques of Zeiss et al. would probably not "survive a malpractice suit by virtue of failure to fully consider potential side effects" (p. 1504). He suggests that clients might look back a year later and find themselves "demeaned," "humiliated," and "suffering irreparable psychological harm." Here we have rhetoric about potential side effects without data. There is no empirical substantiation other than the imagined plea of a counsel concerning "the grievous wounding of spirit." Every one of these legal issues was raised against contraceptive practice, and if persons like Margaret Sanger (Reed, 1978) had not been willing to risk the wrath of others, we would still be in the Dark Ages on that issue. Despite the proliferation of sex therapists, the only legal issues raised in the courts have been those of the use of surrogates and the clearly

unethical practice of sexual relations between therapists and clients (Taylor & Wagner, 1976). Bailey's fears of legal problems are just that—fears.

The privacy issue raised in Bailey's (1978) discussion of legal issues is hard to understand. He argues that unless the "hard" behavioral techniques are "found to be vastly superior" to the "soft" conversational ones, the application of these techniques would be "at worst unethical and possibly illegal, and at best, just bad therapy" (p. 1504). No reason is set forth as to why these techniques must be "vastly superior" rather than just equal. This is a strange double standard—that techniques that use directed masturbation must be vastly superior or else they are unethical. Bailey does not offer a single reason for the necessity of the different standard except the vague argument concerning potential side effects.

The Power Issue

There is not much need to comment here, for Bailey has simply stated that therapists have more power than clients, which is certainly true. He suggests that Zeiss et al. misuse their power, again without documentation except the previously noted assertion that they do not practice on their friends, lovers, and spouses.

The Philosophical-Theological Issue

The sum of Bailey's (1978) argument is that "on the face of it, a masturbation program of any type would appear to carry innumerable hidden messages and covert stipulations—all or most of which are antithetical to Judeo-Christian traditions" (p. 1506). There it is! "On the face of it," masturbation is wrong. Anyone who recommends it, even if it helps people to become well-functioning sexual human beings is guilty of defective professional judgment or to use Bailey's term is *unethical*.

Concluding Comment

Bailey has raised a number of historic concerns about nonreproductive sexual behavior in expressing concern about the use of masturbatory techniques in therapy. His argument is entirely based on potential dangers and on highly charged value judgments. His position is antiscientific, in that it recommends that no new technique be considered until it is proved to be "vastly superior" to conventional techniques. Interestingly, Bailey does not ask for the needed research to be conducted; he argues for sup-

pression of procedures that he finds unacceptable.

Ethical and Professional Issues in Sex Therapy: Comments on Bailey's "Psychotherapy or Massage Parlor Technology?"

G. Terence Wilson
Rutgers—The State University

Sex therapy should be conducted by a skilled therapist who is sensitive to the professional and ethical issues that are inherent in treatment. Potentially adverse side effects of therapy should be continually assessed. To date, however, the findings from sex therapy, including the Zeiss, Rosen, and Zeiss procedure, show predominantly positive consequences. It is imperative that the fully informed client have decision-making primacy in setting treatment goals. Value-free therapy does not exist, and therapists must be careful not to impose their own personal biases. The principle of the least intrusive treatment alternative and the nature of intrusiveness are discussed.

In his response to Zeiss, Rosen, and Zeiss (1977), Bailey (1978) raises some important ethical and professional issues that relate to psychotherapy in general and sex therapy in particular. It is therefore particularly unfortunate that Bailey does more to distort than to clarify the critical issues in a reply that contains irrelevant, arbitrary, and extremist position statements that are empirically unsupported. Nor is a dispassionate appraisal of the issues helped by Bailey's frequently sarcastic tone, which is uncalled for. The following is a brief consideration of some of the points raised by Bailey's objections to Zeiss et al.'s procedures.

Therapeutic Ethics

It is fundamental to the behavioral treatment of sexual (or any other) problems that the client should have the major say in setting the goals of therapy. Accordingly, it is imperative that the fully informed client consents to and participates in goal setting. Informed consent is defined by the criteria of knowledge, voluntariness, and competency (Friedman, 1975). The clients described by Zeiss et al. (1977) sought therapy on a voluntary basis and certainly seem to have been competent to participate in the decision-making process. Along with Bailey, I

assume that they were given a full description and explanation of the treatment procedures. No less is required in order for such methods to be carried out successfully. However, Bailey (1978) criticizes Zeiss et al. for being "totally insensitive to the serious matter of side effects" (p. 1503).

Side Effects of Therapy

Accountability in therapy requires adequate assessment of the behavior that is the target of treatment. Side effects, or changes in behaviors that are not directly targeted for change, are possible in all forms of psychological treatment, including behavior therapy. Accordingly, relevant, related behaviors should be assessed in addition to the specifically treated behavior. Some of these changes may be judged to be desirable, whereas others may not. In behavior therapy, more often than not, these side effects have been positive (Kazdin & Wilson, 1978b). A problem faced by all practitioners is how widely to cast this assessment net in monitoring concomitant or generalized behavior change. Of course, one can always resort to the therapist's clinical acumen and sensitivity in detecting untoward (or positive) consequences of intervention. Although the therapist's judgment is not to be overlooked, more systematic measurement of the broad effects of treatment outcome is needed.

Although no formal guidelines exist, two general classes of behaviors would appear to be directly related to the specific goal of facilitat-

ing coital orgasm in the cases in point. One is the frequency and nature of the clients' sexual behavior as a whole. The other concerns the quality of the clients' emotional and interpersonal relationships with their partners. In this connection it should be noted that Zeiss et al. (1977) obtained pretreatment and posttreatment measures of both marital adjustment and mutual sexual behaviors using widely accepted measurement inventories (Locke & Wallace, 1959; LoPiccolo & Steger, 1974). The increases in marital satisfaction reported by Zeiss et al. are consistent with evidence from other sex therapy programs that have included directed masturbation training (Leiblum, Rosen, & Pierce, 1976). Since *both* partners were actively involved in the treatment program, the therapist had access to another source of clinical data pertaining to treatment effects and was in a favorable position to detect any adverse impact on the clients' interpersonal relationships. To the degree that the therapist, supported by evidence from the inventories, was unable to notice any negative side effects, Bailey's objection is undermined.

One of the problems with Bailey's (1978) reply is that it is consistently negative and does not offer any concrete constructive leads as to how to conduct ethically responsible therapy. For example, he fails to specify *what* side effects are to be feared. Repeatedly, he issues vague, value-laden caveats about sex therapists assaulting "the traditional institutions of marriage, family, and religious values" (p. 1503). He ignores the evidence showing that exposure to pornography does not appear to alter sexual morality (Commission on Obscenity and Pornography, 1970), that the direct behavioral treatment of sexual disorders enhances marital satisfaction and often prevents otherwise certain divorce and family disruption (e.g., Masters & Johnson, 1970), and that serious negative side effects of such therapy have yet to be reported. Quoting questionably relevant position statements by Albee (1977) and by Campbell (1975) is not good enough. At worst it amounts to ill-concealed moralizing.

Nor does Bailey (1978) specify *how* potential side effects are to be assessed or under what conditions sex therapy is ever to be appropriate. Rather, he appeals to therapy performed by "a *psychotherapist* who combines sensitivity to philosophical, moral, and theological issues with his armamentarium of technological skills" (italics added, p. 1505). Who would disagree with this? Reflecting the view of behavior therapists engaged in the treatment of sexual dysfunction, I have previously emphasized that effective

treatment

involves more than instruction in the art of body massage and the use of vibrators. Inadequate interpersonal relationships and lack of communication are more often than not the reasons for sexual distress. Accordingly, sex therapy requires trained therapists who are skilled and experienced. (Franks & Wilson, 1977, p. 401)

Zeiss et al. (1977) explicitly caution that therapists should remain sensitive to these broader and more subtle issues of marital (interpersonal) interaction and self-esteem. Sex therapy does not obviate the need to consider these factors carefully. It often is directly responsible for improving marital harmony, enhancing self-esteem, and providing greater self-fulfillment (Annon, 1974; O'Leary & Wilson, 1975).

If this is so, what then does Bailey find so objectionable? It appears that it is both the goal and the method of Zeiss et al.'s (1977) therapy.

Who Sets the Goals of Therapy?

Behavior therapy requires that the *client* have decision-making primacy in setting treatment goals. The therapist's role is to assist clients in evaluating the probable consequences of different courses of action (Bandura, 1969). In this process the therapist inevitably influences the client (Wilson & Evans, 1976). In doing so, it is crucial that the therapist's biases be recognized and honestly declared. Particular care should be taken in helping the client to differentiate between advice and information that has some empirical basis (in sex therapy, e.g., see Annon, 1974). This candor, in addition to the description of *explicit* treatment methods directed toward *specific* goals in a manner that allows *continual assessment* of progress (accountability), renders viable the notion of informed consent in clients such as those described by Zeiss et al. (1977). In this context the client's goal is to be respected. If the therapist is unwilling to cooperate with the client for either personal or professional reasons, he/she should say so and refer the client elsewhere.

This procedure, with which Zeiss et al.'s (1977) therapy seems to be consistent, can be contrasted with Bailey's caricature and implicit value judgments. His view is that "open season" is being declared on the client; that the treatment is one in which "anything goes" and "no holds are barred"; that therapists like Zeiss et al. are "playing doctor" with "dolllike" clients. Readers may judge for themselves how accurate a representation this is of the Zeiss

et al. procedure in particular or in sex therapy in general. It is my own view that these hyperbolic horrors tell us more about Bailey's personal values than about the treatment and its perception by, and effects on, the clients. Of course, Bailey, or anyone else for that matter, is entitled to be upset by the goals of sex therapy (in this case, the mutual enjoyment of masturbation and coital orgasms by a consenting husband and wife that is made possible by a direct behavioral method). Others, including sex therapists, will find this unobjectionable—even desirable. What is important is that neither view be imposed on the client.

There is a danger that in his no doubt well-intentioned desire to protect clients, Bailey is encouraging the subtle imposition of a particular set of values on clients. The theme that "the therapist knows best" and should be careful before condoning the self-indulgence in his or her clients' runs throughout Bailey's (1978) reply. Nowhere is it more obvious than when he objects to "therapists . . . giving clients what they want (*or think they want*) whether they need it or not" (emphasis added, p. 1503). The implication is clear: The therapist becomes the arbiter of what the client "really" wants and what he/she really needs. Among other contemporary treatment approaches, behavior therapy, in principle, involves a deliberate attempt to avoid this insidious and patronizing attitude. Therapists would do well to take seriously Michel's (1977) reminder that our clients "are the best experts on themselves and are eminently qualified to participate in the development of descriptions and predictions—not to mention decisions—about themselves" (p. 249).

Selecting Treatment Methods: The Criteria of Effectiveness and Intrusiveness

Effectiveness. Given effective methods, ethical and legal considerations dictate that the least intrusive/restrictive alternative be used (cf. Friedman, 1975). In making this point, Bailey concludes that there is no empirical evidence demonstrating the superiority of what he calls "hard" sex therapy procedures over "soft," indirect methods. (For a comprehensive and critical analysis of the evidence bearing on the efficacy of the direct treatment of sexual dysfunction, the reader is referred to Franks & Wilson, 1977; Kazdin & Wilson, 1978b; and Marks, 1976.) Suffice it to state here that there are studies indicating the greater efficacy of direct (behavioral) compared to indirect (verbal psychotherapy) techniques (Lazarus, 1961;

Marks, 1976; Obler, 1973) or a waiting-list control group (Munjack et al., 1976). Moreover, the more direct ("harder") the method, the greater the apparent efficacy (Kockott, Dittmar, & Nusselt, 1975; Mathews et al., 1976). This latter tendency is consistent with the more general finding that performance-based (direct) methods are more effective than those that rely on verbal or vicarious procedures (cf. Bandura, 1977a; Wilson, 1978).

There are as yet no unambiguous data showing that orgasmic reconditioning significantly alters sexual behavior (Conrad & Wincze, 1976). However, uncontrolled clinical reports continue to suggest that it may be a useful method (e.g., Lobitz & LoPiccolo, 1972; Wilson, 1973). Although most of the evidence for the efficacy of behavioral methods rests primarily on uncontrolled clinical reports, evaluation of the rules of evidence must take into account the fact that the consistently high success rates that have been reported by widely differing programs are unprecedented (e.g., Kaplan, 1974; Masters & Johnson, 1970). Nothing like it has ever been reported even with highly selected clients in uncontrolled clinical reports (O'Leary & Wilson, 1975). Although the final verdict must await the appropriate controlled outcome studies, the available evidence unquestionably indicates that direct performance-based methods are the *only* reasonable alternative for treating most forms of sexual dysfunction.

Intrusiveness. Bailey's assumption is that direct sex therapy methods such as orgasmic reconditioning are highly intrusive while traditional psychotherapy is not. The issue is more complex than this simplistic dichotomy implies, however. Orgasmic reconditioning is a well-specified technique that is *self-administered* by two informed sexual partners. It has a limited goal (orgasm); its effects on sexual behavior are reasonably predictable and clearly observable to the client. Is this what intrusiveness means? Simply because it is a direct behavior change method that involves sexuality does not necessarily make a technique intrusive.

Compare these procedural criteria with traditional psychotherapy. The success of psychodynamic therapy is predicated on the development of a workable transference relationship.¹ During

¹ Interestingly, a major reason why Masters and Johnson (1970) emphasized the importance of a dual-sex therapy team was to avoid the development of a transference relationship. Their treatment is geared to enhancing emotional communi-

the course of this intense emotional relationship, unconscious thoughts, forbidden impulses, hidden fantasies, and a wealth of deeply intimate material are probed. Therapy has the relatively vague goal of insight without specific operational referents that are immediately observable to the client (cf. Bandura, 1969). Could this not be construed as intrusive? Is this approach not more likely to delve into "life's elusive purpose" than the limited attempt to enhance orgasm during coitus? The answers to these questions will vary depending on the specific circumstances of each case and cannot be brushed aside by oversimplifications about what at face value seems to be the case.

Causal Models and the Therapeutic Relationship

Bailey (1978) portrays therapy as a process in which extremely powerful treatment methods are administered to dolllike clients by omnipotent therapists who "extract levels of 'obedience' that Milgram could only dream of" (p. 1504). Although this view is occasionally shared by some proponents and opponents of behavior modification alike, it fares poorly under critical scrutiny. Bandura (1978) has discussed the conceptual inadequacies of this sort of unidirectional causal model of human behavior, making a compelling case for the reciprocal determinism of behavioral influence. The therapist's influence may be considerable, but it is far from total. (See Davison, 1973, and Wilson & Evans, 1976, for a fuller discussion of the ways in which the therapist may influence the client, how unilateral therapist control is limited, and why self-regulated change is preferable to external influence.) It is more realistic, not to mention more humble, to note that the therapist is more a consultant than a controller, skillfully directing consciously involved clients in active, self-regulated problem-solving strategies instead of dominating puppetlike figures through "almost hypnotic power."

Conjuring up images of automatic conditioning, obedience training, and master-slave relationships makes for lively polemics but faulty psychology (Bandura, 1977b). The sense of this discussion can be summarized by observing that considerations of both ethics and efficacy require a therapeutic relationship in which the client is an active, self-directed participant.

cation between the clients themselves. This would be impeded by the client forming an emotional attachment to the therapist.

Concluding Comments

Bailey's response contains several irrelevant and arbitrary assertions that despite his disclaimer, could be read to impugn the professional ethics of sex therapists. Two of the more obvious examples can be mentioned. First, it is difficult to see how the issue of sexual contact between therapist and client is relevant to a serious analysis of the Zeiss et al. (1977) procedure. This is a mischievous juxtaposition that may mislead by "guilt through contiguity." Second, there is the allegation that sex therapists hold to a double standard of ethics in practicing massage parlor technology on clients who are strangers while shunning the same methods with their "loved ones." In fact, I know of cases that contradict this claim. If the reader finds my own subjective observation less than convincing, then my point about Bailey's speculation has been made.

Unquestionably, sex therapists should monitor both the direct and indirect effects of their treatment methods on clients' functioning. This attention to potential side effects of therapy should be part of an expanded evaluation of psychotherapy within a broader set of criteria than has usually been the case up to now (cf. Kazdin & Wilson, 1978a). The consequences of a pluralistic society are that different cultural groups will have different social values that are sometimes difficult to reconcile. There is no such thing as value-free therapy, and the impact of the therapeutic process on personal and social mores requires constant attention and analysis. In part, the resolution of these thorny issues will depend on their public airing as in the present interchange of ideas.² However, it is my contention that the judicious use of direct behavioral methods for the treatment of sexual dysfunction by a skilled therapist who is sensitive to these ethical issues constitutes sound clinical practice. The benefits to our clients are often considerable, and I suggest that the onus is now on those who would oppose these methods to show sufficient cause for continued recalcitrance.

² The questions of ethics, social norms, and the goals of treatment in sex therapy have been considered elsewhere (cf. Davison & Wilson, 1974; Garfield, 1974; Kohlenberg, 1974; Strupp, 1974). The present discussion should be viewed in this broader context of ethics and sexual behavior change.

Comments on Levin et al. and Rosen and Kopel: Internal and External Validity Issues

Gary M. Farkas
University of Hawaii

This comment discusses problems of internal and external validity relevant to applied laboratory research in the modification of sexual behaviors. Used as examples are two recent case studies published in this journal. Suggestions are presented for improving the internal validity and the generalizability of studies using the laboratory paradigm.

In a recent issue of this journal, Levin, Barry, Gambaro, Wolfensohn, and Smith (1977) and Rosen and Kopel (1977) presented attempts to modify sexual response in two patients. Levin et al. sought to reduce the degree of penile response to pedophilic stimuli in a man with a 19-year history of pedophilic behavior. Rosen and Kopel attempted to modify tumescence in a man who had exhibited both transvestite and exhibitionistic behavior for 30 years. Each group of authors reported apparently successful treatments with regard to those measures assessed.

The issue for discussion in this comment will be the selection of dependent variables, both during baseline measurement and with regard to the wider issues of external validity. Although the previously cited articles are the subjects of this reply, they exemplify other studies that have similar shortcomings.

The primary purpose of baseline measurement is to provide a reference by which treatment efficacy can be evaluated. Thus, pretreatment measures provide an internal validation of an intervention's effect. One might question, however, the relevance of the pretreatment conditions used in these studies as a check for internal validity. In this discussion, I will examine only one of the measures used—percentage of full erection to deviant stimuli.

In Levin et al. (1977) and Rosen and Kopel (1977) the primary threat to internal validity was the ability of males to possess inhibitory

control over tumescence. This skill has been shown by normal subjects (Henson & Rubin, 1971), and may result from cognitive mediation (Farkas, Sine, & Evans, in press). Both Levin et al. and Rosen and Kopel made a crucial error in assuming that incarcerated patients subject to contingencies of the judicial system would provide truthful data. Since this is unlikely, some measure of deception is needed. For these particular patients, the index would be the degree to which they possessed voluntary control of tumescence to problematic stimuli.

If, for example, a patient exhibits the ability to suppress arousal to 50% of full tumescence, should not therapy be designed to enhance this skill and assessment be formulated to measure the effect of therapy above and beyond that ability presented de novo? To my knowledge, no single case or group study has taken this voluntary control issue into account.

There are additional problems of external validity that necessitate response. As Rosen and Kopel (1977) noted, strain gauge measurement is a precise and reliable indicant of physiological sexual arousal; however, the degree to which this measure provides externally valid evidence of behavior change is subject to several challenges. First, whereas tumescence may provide the first and most reliable physiological index of arousal (Zuckerman, 1971), it does not provide a measure congruent with self-report. Farkas et al. (in press) have demonstrated that under ideal conditions, the correlation between these measures averages .46, with considerable variability. Moreover, these authors maintain that a high degree of subjective arousal may be reported while minimal tumescence is evident.

Second, to what degree is penile arousal an essential criterion of sexual behavior? Stated differently, is there evidence that modification

The author is indebted to Raymond C. Rosen and Jack S. Annon for their contributions to his learning experience.

of penile responsivity in laboratory settings predicts overt behavioral changes in extralaboratory environments? Much data, both in biofeedback and aversion therapy studies of sexual problems, indicate that this is not necessarily the case (e.g., Barlow, Agras, Abel, Blanchard, & Young, 1975).

A final issue concerning generality regards the external validity of the treatment stimuli compared to stimuli encountered in the natural setting. Certainly, slides of nude girls and videotapes of transvestism-exhibitionism are unlike those stimuli evoking problematic behaviors in the extralaboratory situation. Thus, just as we have witnessed a generalization gradient to non-treatment slides (e.g., Levin et al., 1977), how steep will this gradient become when extralaboratory cues are assessed?

The present experimental literature suggests extreme caution in interpreting studies that examine reduced tumescence response to problematic stimuli as a function of some treatment. However, if one continues to accept the laboratory paradigm as having utility in treatment studies, what modifications in procedure might prove useful?

First, given the finding of unreliability between self-report and tumescence, an assessment of this factor for each patient would be valuable during the prebaseline phase to establish an upper limit of confidence in the generalizability of the data.

Second, therapists should assess the degree of inhibitory control that clients possess at prebaseline measurement. For the incarcerated patient with a high degree of voluntary control, the internal validity of any treatment effect measured by this method would be seriously questioned.

Third, the nature of the arousing stimuli used should be modified. Most often, arrests are made not because of arousal to media presentations in laboratories but because of problematic behaviors elicited by highly individual cues in the external setting. At this juncture, Abel's method of cue generation (Abel, Blanchard, Barlow, & Mavissakalian, 1975) appears to hold the most promise, at least when tumescence is the focus of intervention.

Finally, tumescence responses rarely appear to constitute the only behavior leading to in-

carceration in cases of sexual problems. Rather, a complex series of motor behaviors (e.g., fondling young children) appears to contribute to, or wholly constitute the basis for, society's unwillingness to accept certain aberrations. Thus, should not these motor behaviors be appropriate targets for direct intervention? Targeting penile response without concomitant attempts to modify cognitive and behavioral factors that may co-occur or predominate as the basis for maladaptive sexual behaviors does not appear to hold promise for maintenance and generalization of appropriate responses in the natural situation.

Although direct measurement of sexual arousal has proved a welcome innovation, the limitations of the method must be recognized. With continued discussion and experimental refinements, it is hoped that the validity of this method will improve and that more effective treatments will be developed.

motor, and physiological responses. In our study we used all three measures to support the inference of therapeutic change. We were able to demonstrate decrements in pedophilic tendencies during and immediately after treatment and on extended follow-up, with changes evident in penile measures, self-report, and also on necessarily indirect measures of motor behavior. The last index is perhaps most important, since the ultimate criterion is whether or not the patient molests children or gets into other difficulties following treatment. At last report, our patient had not done so. Farkas (1978) implies overemphasis on the penile measure, which we feel is not the case.

A final point needs to be made regarding a possible misunderstanding on Farkas' (1978) part. In discussing the importance of treating motor behaviors, he says,

Targeting penile response without concomitant attempts to modify cognitive and behavioral factors that may cooccur or predominate as the basis for modification of sexual behaviors does not appear to hold promise for maintenance and generalization of appropriate responses in the natural situation. (p. 1516)

This implies that we used penile response as the reaction to be treated. This is not the case. In treatment we used imagined versions of real-life situations that had in the past, and might in the future, serve as occasions for sexual attraction to children. We also instructed the patient to imagine the pedophilic thoughts and fantasies that occurred in these situations.

In summary, changes in penile erection measures obtained in a laboratory setting are obviously not to be regarded as the sole criterion of therapeutic change. Such measures need to be supplemented with self-report techniques and

evaluations of motor behavior. The fact that erection can be voluntarily controlled is, indeed, a problem that may very well be almost impossible to get around (Laws & Holmen, Note 1). As Farkas himself seems to suggest, it may be best to capitalize on such control by using it in treatment instead of regarding it as an assessment problem.

Role of Penile Tumescence Measurement in the Behavioral Treatment of Sexual Deviation: Issues of Validity

Raymond C. Rosen and Steven A. Kopel

Department of Psychiatry, College of Medicine and Dentistry of New Jersey
Rutgers Medical School, Piscataway

Farkas has raised three specific issues concerning the validity of penile tumescence assessment of sexual arousal in the laboratory. Some of these issues had been addressed in our original case study, and this reply to Farkas is intended to place the issues of validity in a broader perspective. While acknowledging the limitations of the erection measure, we nevertheless see an important place for it in both the assessment and treatment of sexual disorders.

In Rosen and Kopel (1977), we reported the results of a case study using penile tumescence measurement and biofeedback to modify the transvestite/exhibitionistic pattern in a 45-year-old male client. Despite an initial positive outcome, remission of the deviant behavior was reported to us by the client's spouse approximately 2½ years after treatment. Farkas (1978) has raised issues concerning the validity of the tumescence assessment as described in Rosen and Kopel, in addition to the broader issues of the usefulness of tumescence measurement in clinical studies. Some of the issues addressed by Farkas had, in fact, been dealt with in our original study. However, the validity issues that have been raised deserve a broader perspective than that offered by Farkas. The purpose of this reply is to examine the question of validity of tumescence measurement in greater depth.

To begin with, it is worth considering the growing appeal of penile plethysmography as a laboratory assessment measure. Rosen and Keefe (in press) have reviewed the burgeoning field of tumescence measurement and have concluded that it is a key dependent measure for assessment of male sexual arousal. Historically, the need for objective determination of sexual preference and response has led to less reliance on self-report and greater interest in direct measures of sexual arousal (Zuckerman, 1971). Especially when treating a sex offender, there are obviously good reasons for supplementing the

client's self-report with objective physiological assessment. In fact, good clinical practice dictates the use of *multiple* criterion measures for a comprehensive assessment of clinical outcome (Keefe, Kopel, & Gordon, 1978). For example, in our case study we described the use of a standardized paper-and-pencil instrument for evaluation of sexual interaction (LoPiccolo & Steger, 1974), subjective ratings of arousal to erotic stimuli, client and spouse reports of marital/sexual satisfaction, and laboratory tumescence assessments.

Regarding the validity of tumescence measurement, Farkas (1978) raises three specific issues: (a) The fact that males are able to exercise *some* degree of voluntary control of tumescence (Henson & Rubin, 1971; Rosen, 1973) is presented as a threat to the internal validity of the measure. (b) With respect to external validity, Farkas challenges the association between strain-gauge data and self-report of overt behavior. and (c) The generalization from laboratory to "real-life" stimuli is viewed as a further threat to external validity. We will deal with each of these three issues in turn.

Levin, Gambaro, and Wolfensohn (1978), in reply to Farkas (1978), have pointed out logical inconsistencies in the suggested independent assessment of voluntary control of penile response. The potential for response "faking" is just as relevant to "prebaseline assessment" as it is to subsequent measurements. Thus, although we agree that clinicians and researchers need to be concerned with voluntary control of tumescence, Farkas' suggestions do not appear to offer a real solution. Further, in our case study we examined several sources of evidence regarding the possibility of tumescence faking.

Requests for reprints should be sent to Raymond C. Rosen, Department of Psychiatry, College of Medicine and Dentistry of New Jersey, P.O. Box 101, Rutgers Medical School, Piscataway, New Jersey 08854.

From the gradual, progressive learning curve [of penile tumescence] it appears unlikely that suppression of response was due to distraction or demand characteristics . . . Furthermore, the client's subjective ratings of arousal changed more gradually than actual penile responses—further evidence against an explanation in terms of demand characteristics. Finally, penile tumescence suppression continued to improve even below the limit of sensory awareness (approximately 10% full erection). (Rosen & Kopel, 1977, pp. 914-915)

The second issue, the *external* validity of tumescence measurement (i.e., the notion of response generalization), is complex and merits further discussion. In part, this concern involves the consistency between physiological, self-report, and overt behavioral indices of sexual response. According to Farkas, the correlation between self-report and tumescence is weak. However, other researchers (e.g., Abel, Blanchard, Murphy, Becker, & Djenderedjian, in press) have found *strong* associations between these two measures. Furthermore, with respect to the relationship between laboratory control of tumescence and subsequent overt sexual behavior in the natural environment, other reports (e.g., Csillag, 1976) have shown meaningful generalization. Thus, there is independent empirical support for the external validity of the tumescence measure. However, in any given instance, external validity should not be taken for granted. Rather, clinicians or researchers should seek independent evidence for convergent validity (Campbell & Fiske, 1959) across response measures through a multiple-criterion assessment package.

In the treatment of sexual deviations, one frequently encounters a lack of consistency (i.e., divergence) across response systems. For instance, a number of exhibitionists treated in our clinic have exposed themselves in public without any evidence of concomitant erection or orgasm. In such cases it appears that the inappropriate behavior is functionally independent of genital response, and therefore tumescence measurement may not always be relevant. In the case study (Rosen & Kopel, 1977), however, erection and orgasm were critical components of the deviant pattern, and therefore were included in both assessment and treatment.

The third issue raised by Farkas (1978) is the question of stimulus generalization from laboratory to real-life stimuli. Our concern with this issue was reflected in our selection of assessment and treatment stimuli. For example, with respect to the client's transvestite pattern, we used his actual transvestite garments in assessment of sexual arousability. It is noteworthy that tumescence measurement revealed that contrary to our

expectations, fondling of these garments with active imagery failed to elicit arousal. However, subsequent videotaping of the complete transvestite-exhibitionistic script did prove to be a reliable eliciting stimulus for tumescence response. This suggests that the issue of real-life versus laboratory stimuli raised by Farkas may be an oversimplification. The videotape, although a more *contrived* stimulus in some respects, appeared to incorporate subtle but critical parameters of the real-life pattern. It appears from this case that treatment stimuli should not be selected a priori but rather should be determined by an empirically based, comprehensive assessment.

Finally, the unsuccessful long-term result reported in our case study raises the possibility that too much reliance was placed on penile plethysmography in assessment and treatment. On the contrary, after intensive review we have concluded that the *absence* of tumescence assessment beyond the initial 4-month follow-up period was a strategic error. Our reliance on the client's self-report during the subsequent 2-year period provided a series of false outcome assessments. We believe that tumescence measurement, as originally used, might have cued the therapists to the gradual return of the deviant arousal pattern, thus providing a critical opportunity for reinstatement of the treatment program.

A Note on Psychosomatic Factors in the Etiology of Neoplasms

Jonathan Kellerman
Division of Hematology-Oncology
Children's Hospital of Los Angeles
Los Angeles, California

Watson and Schuld attempted to study the relationship between psychopathology and subsequent development of neoplasms. Their results, which indicated no apparent connections between these variables, are limited due to methodological flaws, both relating to sample selection. The study sample, composed of psychiatric patients, was highly restricted along one of the variables studied—psychopathology—and was further confounded by uneven distribution of a potentially carcinogenic factor—alcoholism. Though there is no empirical evidence of psychological causation of neoplasms, the Watson and Schuld study is not the one to lay this issue to rest.

The recent study by Watson and Schuld (1977) concerning the relationship between psychopathology and subsequent development of malignant and benign neoplasms deserves credit for attempting to test several psychosomatic theories in a prospective manner. In this way, the authors commendably strove to eliminate methodological problems inherent in retrospective studies. Unfortunately, while dealing with one set of confounding variables, Watson and Schuld have neglected to consider another: the issue of restricted sample.

In the discussion of their results, Watson and Schuld made note of several caveats regarding their results, including possible weaknesses of the Minnesota Multiphasic Personality Inventory as a comprehensive catalogue of personality traits, premorbid differences between groups on variables not measured, and inability of such a study to address the issue of immediate premorbid loss of trauma. (To this last factor I would add that the study can say nothing *whatsoever* with regard to premorbid loss, *immediate or otherwise*.) They neglect, however, to consider the effect of using a sample of psychiatric inpatients as subjects.

In view of the specialized nature of the sample, it is not surprising that no significant dif-

ferences in psychopathology were found between groups. The basic finding of Watson and Schuld's (1977) study is that among a group of individuals for whom psychopathology had been diagnosed, the *degree* of psychopathology was not related to subsequent development of neoplasms. This is quite different from comparing groups of pathological versus nonpathological individuals and making a statement regarding psychopathology in the general (nonhospitalized) population. The use of a sample of people who represent a highly specialized subsample along the distribution of one of the major variables in the study (psychopathology) places strong limitations on the kinds of conclusions that can be drawn from Watson and Schuld's results. The only justifiable conclusions derived from the data are with regard to the degree of psychopathology within a pathological subgroup as it relates to neoplastic vulnerability.

In addition, the use of subjects suffering from alcohol-related problems injects another confound into Watson and Schuld's (1977) results in that such individuals may be more prone to specific types of malignancies, and this factor may obscure or outweigh any psychopathology-neoplasm relationship. In fact, these individuals are overrepresented by a ratio of 6:1 within the malignant group.

This is not to say that there is a great deal of prospective, objective data in support of psychopathological theories of neoplastic etiology such as that of Bahnson and Bahnson (1966), for there is not, and work is needed in this area. Such research, however, will need to carefully

consider quality of sample in order to avoid the severe attenuation of results that Watson and Schuld's (1977) study falls victim to.

Psychosomatic Etiological Factors in Neoplasms: A Response to Kellerman

Charles G. Watson
Veterans Administration Hospital
St. Cloud, Minnesota

Donald Schuld
Faribault County Human Services Center
Blue Earth, Minnesota

Kellerman argues that our use of psychiatric patients in a study designed to search for psychosomatic etiological factors in neoplasms may have led to our negative results. However, we suggest that the use of psychiatric patients increased the heterogeneity of the sample and probably enhanced, not limited, the likelihood of positive findings. He also suggests that our inclusion of alcoholics in the study may have masked real differences between neoplasm and control subjects. However, new analyses run on subsets of our malignancy and malignancy-control samples from which alcoholics were first deleted failed to support his contention. New analyses run to test for differences between the frequencies of various high-scale Minnesota Multiphasic Personality Inventory types in neoplasm and control groups also failed to support the view that neoplasm patients are qualitatively different from controls on the inventory.

In an earlier article (Watson & Schuld, 1977), we described a study comparing the diagnoses and Minnesota Multiphasic Personality Inventory (MMPI) responses of psychiatric patients who later developed neoplasms to those of psychiatric controls who did not. We found a considerably smaller number of significant differences between the two groups than would have been expected to appear on a chance basis, and we concluded that our results failed to support the increasingly popular theory that such growths are psychogenic.

Kellerman (1978) argues that our negative results may reflect the use of a "highly specialized" psychiatric sample and that we should have used a psychologically normal sample instead. He suggests that the homogeneity that can be inferred from the limitation of the sample to psychiatric patients may have attenuated relationships between neoplasm proneness and psychological dimensions. We believe, however, that our samples showed considerably more diversity in type of pathology than one would expect to

find among normals, including, as it did, schizophrenics, manic-depressives, involutional psychotics, neurotics, alcoholics, personality disorders, and brain-damaged patients. In fact, this heterogeneity may have increased the probability of significant neoplasm-personality relationships beyond that which might have been expected among normals. We would expect such relationships to be most conspicuous in samples with diverse and substantial amounts of psychopathology, and we suspect that our choice of a psychiatric ward sample enhanced—not reduced—the probability of positive results. Despite this presumed bias, our results were strikingly negative.

Kellerman (1978) also criticizes the inclusion of alcoholics in our samples. (Six appeared in our malignant neoplasm group and one among its controls.) He notes that since large quantities of alcohol may be carcinogenic, their inclusion might have obscured psychopathology-neoplasm relationships. If his reasoning is correct, it seems to us that if anything, the inclusion of alcoholics should have *increased* the probability of our finding relationships between personality types and neoplasm proneness, since more alcoholics appeared in the malignancy sample than in its controls. Despite this (possible, at least) bias toward positive results, our results were negative. Nevertheless, we have recalculated *t* tests for MMPI scales in subsamples of our malignancy and malignancy-control groups from which

subjects with alcohol-related diagnoses were first deleted. These analyses were based on 28 subjects, 14 from the malignancy group and 14 controls matched with them for age. None of the 13 resulting *ts* (which ranged from .06 to 1.55) run to test for differences between the MMPI scale means of the samples was significant, even at the .10 level. The view that our negative findings resulted from the physical effects of alcohol was not supported.

The Kellerman (1978) critique's emphasis on our finding that the relationships between neoplasm proneness and degree of pathology were low suggests the possibility that neoplasm risk may be related to *quality*, rather than amount, of measured psychopathology. Since we used a wide variety of (qualitatively different) dependent variables—eight diagnostic categories, 13 MMPI scales, and several hundred individual MMPI items—and found little evidence that any of these variables is related to neoplastic vulnerability, we have been skeptical about the possibility that qualitative differences exist. Nevertheless, we have run additional analyses to test for them.

To evaluate the qualitative difference hypothesis, we determined the two highest MMPI clinical scale *T* scores for each subject and compared their frequencies in our neoplasm and control samples with sign tests. Only 1 of the 20 sign tests (10 each for malignant/malignant-control and benign/benign-control comparisons) was significant at the .05 level. No significant differences were associated with malignant growths, but Hysteria (*Hy*) peaks were less common ($p =$

.02) among patients who later developed benign growths than among their controls. Since high *Hy* scores are generally positively correlated with psychosomatic tendencies, and since only 1 of the 20 differences was significant, these findings offer little support for the suggestion that our earlier procedures may have masked qualitative differences between neoplasm and control samples or the view that neoplasms are psychogenic.

Kellerman (1978) is correct in noting that our results can be generalized only to psychiatric patients. However, our negative results in psychiatric subjects, and the absence of any prospective study that has shown premorbid differences between neoplasm and appropriate control patients on either personality inventories or blind ratings of projective tests, lead us to doubt that important neoplasm-psychopathology relationships will emerge among normals, since both the quantity and diversity of psychopathology in the latter group is limited. Nevertheless, the question is ultimately an empirical one, and the issue will have to be resolved with additional studies, rather than speculations such as those offered by Kellerman and by us.

The Therapist-as-Fixed-Effect Fallacy in Psychotherapy Research

Colin Martindale
University of Maine

Studies of psychotherapy involve sampling two sets of subjects from two populations: patients and therapists. Conclusions about psychotherapy should thus be based on statistical evidence that results are reliable across both patients and therapists. In most published research concerning psychotherapy, no statistical evidence is provided that findings can be generalized beyond the particular sample of therapists studied. In spite of this, researchers tend to draw conclusions concerning psychotherapy and therapists in general. Analysis of variance designs that allow generalization of results across both therapists and patients are described. The serious problems with inappropriate analyses of variance—treating therapists as a fixed effect or ignoring the therapist factor altogether—are discussed. A review of recently published studies of psychotherapy reveals that most researchers have done one or the other of these inappropriate analyses.

Psychotherapy and related procedures involve two participants or sets of participants, therapists and patients. Consequently, the researcher who wishes to study psychotherapy is faced with the necessity of generalizing findings to two populations: a population of therapists and a population of patients. To do this, it is necessary to select random samples of both patients and therapists and then to perform statistical analyses that will provide assessments of reliability for both samples. However, the majority of studies on psychotherapy concentrate solely on reliability across patients. The consequence is that most of these studies tell us nothing about psychotherapy in general and a lot about whether the particular results found would probably be reproduced with a new sample of patients seen by exactly the same therapists who were used in the study. However, these studies have for the most part been presented and accepted as if they answered more than this question.

In analyses of variance of data concerning psychotherapy, therapist effects have been improperly handled by either treating the therapist factor as a fixed effect or by ignoring the therapist factor altogether. When therapist ef-

fects are handled in either of these ways, it is impossible to generalize results beyond the immediate sample of therapists used in one's study. This comment presents no original ideas or methods; it is merely a reminder to psychotherapy researchers that they tend regularly to use the analysis of variance in what is known in other contexts to be an inappropriate manner. Since this inappropriate usage can drastically inflate the possibility of Type I errors, the reminder would seem to be in order.¹

Fixed Versus Random Factors

Factors in analysis of variance are either fixed or random. In general, a factor is fixed if all treatment levels of interest are included in an experiment, whereas a factor is random if its treatment levels are drawn at random from a larger population of possible levels. It is clear that in research on psychotherapy there must be two random factors: therapists and patients.

¹ The necessity for generalization to more than one population is not unique to psychotherapy research. Clark (1973) has pointed out almost the same problems in psycholinguistic studies in which it is necessary to generalize to both populations of words and of subjects. Brunswik (1947), Hammond (1954), and Rosenthal (1966) have also dealt with the necessity of generalizing to more than one population in a variety of situations.

This has crucial implications for the choice of correct error terms in analysis of variance. In an analysis in which subjects are the only random factor, error terms are derived from estimates of within-cell variation. The degrees of freedom of these terms are dependent on the number of subjects. However, in analyses in which there are random factors besides subjects, this is not the case. Many error terms are not properly derived from within-cell error, and the degrees of freedom of these terms are not dependent on the number of subjects but on the number of levels of the other random factors.

Consider an experiment comparing the relative effectiveness of psychoanalysis and covert sensitization. There are several ways of designing such an experiment. In a crossed design, one randomly selects n therapists and N patients. All n therapists perform both types of treatment, and a subset of patients is assigned to each of the therapist-treatment combinations. If the therapist factor is taken as a random one, then to assess treatment effects, an F ratio is formed by dividing the treatment mean square by the Treatment \times Therapists mean square, with $df = 1$ and $n - 1$ in the case of two treatments. For one reason or another, it may be preferable to use a hierarchical design in which n therapists are nested under the two treatments. For example, n_1 therapists could be assigned to do covert sensitization, and n_2 different therapists could be assigned to do psychoanalysis. The N patients would be assigned at random to therapists as above. In this case, the correct denominator for the treatment mean square is the therapists within treatments mean square in forming an F to assess the main effect of treatments. In the case of two treatments, this denominator will have $2(n_1 - 1)$ degrees of freedom. In this analysis, one collapses over patients altogether in making the analysis. It does not matter whether each of the n therapists sees one or a thousand patients. A third possible design would involve a completely randomized one-way analysis of variance. This would necessitate random selection of n therapists and N patients (where $n = N$), random pairing of therapists and patients, and random assignment of these pairs to the two treatments. In this case the treatment effect is assessed against the within-cell mean square with $n - 2$ degrees of freedom for the case of two treatments. These are elementary considerations that are discussed in detail in any standard book on design such as Winer (1971) or Kirk (1968). The important point is that in each case, the effective upper limit on degrees of freedom is given by n rather than

by N . The number of therapists in one's study—not the number of patients—determines the degrees of freedom of F ratios and, hence, their power.

Typical Problem and Appropriate Solutions

If the effective N for a therapy study is n rather than N , and if it is difficult to obtain large numbers of therapists, then one is faced with a problem. An inherently variable event such as psychotherapy process or outcome intuitively calls for a large number of degrees of freedom if tests of hypotheses are to have much power. Where are these degrees of freedom to come from? The only fully satisfactory solution is to design one's study to include a lot of therapists. If this is not possible, the only legitimate hope is that if n must be small, one could pool. To do so, interactions of treatments with therapists or therapists-within-treatment effects must be small. In a crossed design, if the Treatment \times Therapists interaction can be shown to be zero, at a liberal α , it may be legitimate to pool the sum of squares for Therapists \times Treatments with the within-cell sum of squares to obtain a within-cell mean square estimate with a larger number of degrees of freedom for testing all effects. In a hierarchical design, it would be necessary to show that the therapists-within-treatment effect was zero. Then, this sum of squares could be pooled with the within-cell sum of squares. In either case, to avoid Type II errors (accepting the hypothesis that the effect in question is zero when it should be rejected), it is necessary to test the hypothesis that the effect to be eliminated is zero at a high value of α : Kirk (1968, p. 215) suggests $\alpha = .25$, but Winer (1971, p. 379) suggests $\alpha = .20$ or $.30$ for such tests. It is inappropriate to use $\alpha = .05$ or $.01$ for such tests, since this would inflate the probability of Type I errors in tests of treatment effects beyond the nominal α for such tests. It should be noted that many statisticians advocate a conservative "never pool" approach, and even those with a more moderate attitude advise against pooling effects when there is any a priori reason to expect that such effects might exist. Given this, pooling involving Treatment \times Therapists interactions or therapists-within-treatment effects must always be viewed as an extremely "liberal" practice.

Inappropriate Analyses

Treating the Therapist Factor as Fixed

There are several inappropriate solutions to the problem. One obvious solution is to treat

the therapist factor as fixed rather than random. In this case, the divisor in obtaining the F ratio for treatments will always be the within-cell mean square, which will have degrees of freedom primarily dependent on N rather than n . The problem with this solution is that it completely destroys the scientific value of the study, since all conclusions must be restricted to the particular therapists used in the study. (Of course, if one were deliberately carrying out a study of a specific set of therapists, as in a program evaluation, it would be quite proper to treat the therapist factor as fixed.)

Psychotherapy researchers who explicitly include a therapist factor in their analysis of variance designs do in fact tend to regard this factor as fixed. That this has serious effects can be demonstrated by a reanalysis of the data from several well-known studies. Paul (1966) investigated the efficacy of two types of therapy (desensitization and insight) and an attention-placebo control treatment. Five therapists each saw three patients in each of the three treatment conditions. Patients were assigned at random to these conditions. This was a crossed design: Therapists were crossed with treatments, and patients were nested under Therapists \times Treatments. Paul treated the therapist factor as fixed and obtained a number of F ratios for treatment effects. These F s were obtained by dividing the treatment mean square by the

^b Therapists random.

* $p < .05$.

** $p < .01$.

within-cell mean square. Significant F s from the Paul study are given in Table 1. It may be asked, what would happen to the F s if we were willing to believe that therapists were selected at random? The answer is shown in the second column of Table 2. The F s here were obtained by dividing the treatment mean square by the Treatment \times Therapists mean square. Two of the F s are no longer significant ($p > .05$), and p falls from less than .01 and .001 to less than .05 for the others. Paul's original F values tell us what would probably happen if his study were replicated with exactly the same therapists and different patients. Our F values tell us what might be expected if his study were replicated with other therapists and other patients.

An example of an often-cited hierarchical study in which the therapist factor was fixed was done by Truax et al. (1966). The study concerns four psychiatrists who were rated on the therapeutic conditions of accurate empathy, genuineness, and warmth. The psychiatrists were placed into a group that offered high levels of these conditions and a group that offered low levels. Each of the therapists saw 10 patients, half of whom had previously undergone a "role induction" interview and half of whom had not. Thus, therapists were nested under levels of therapeutic conditions; therapeutic conditions and therapists within therapeutic conditions were crossed with role induction; and patients were nested under Therapists \times Role Induction. Truax et al. treated therapists as fixed and thus

Table 1

Analyses of Variance of Therapist Ratings of Six Dependent Variables From Paul (1966)

Treatment effect	Therapist fixed	Therapist random
	F ^a	F ^b

Appropriateness of length of therapy	12.51***	5.39*
Therapist comfort	8.15***	4.11

^a df = 2, 30.

^b df = 2, 8.

* $p < .05$.

** $p < .01$.

*** $p < .001$.

used the within-cell mean square to test all effects and interactions.

Results of their analysis of therapist ratings of global improvement are given in Table 2. If therapists are treated as random rather than fixed, then the correct divisor for the conditions mean square is the therapists within conditions mean square, and the correct divisor for the role induction mean square and for the Conditions \times Role Induction mean square is the Role Induction \times Therapists Within Conditions mean square. Results when the therapist factor is taken as random are shown in the last column of Table 2. As can be seen, none of the F s even approach significance. Truax et al.'s results apply only to the four therapists in their study. There is no reason to expect them to replicate.

Ignoring the Therapist Factor

Another illegitimate approach is to ignore therapists altogether in the analysis. That is, one might do a study involving a crossed or hierarchical design and then analyze it as if it were a completely randomized one-way design. This is, of course, incorrect for a variety of reasons. Not the least of these reasons is that in doing this, nonindependent observations are treated as if they were independent. The numbers in psychotherapy research are often things such as ratings of improvement by therapists. If one therapist makes more than one of these ratings, then these ratings cannot be expected to be independent. Inclusion of a therapist factor allows the researcher to take account of this. One ought to include in an analysis all factors that might reasonably be expected to have some systematic effect. It would be difficult to argue that individual therapists would have no such effect.

It is quite true that ignoring a relevant source of variation in analysis of variance will generally inflate the within-cell error term, but this is beside the point if the correct error term is not used in the first place. For the types of designs that I have been discussing, it is definitely not the case that the within-cell mean square will be inflated sufficiently to allow its use. In fact, as N becomes large, one virtually guarantees a significant treatment F even given that the treatments variance is 0 if there are any therapist differences in effectiveness.

Because ignoring the therapist factor leads to a loss of necessary error terms in an analysis in which the therapist factor is random, it involves an implicit assumption that therapists constitute a fixed factor and is inappropriate for the rea-

sons already given. Finally, ignoring the therapist factor leaves no statistical way of specifying the generality of our findings vis-à-vis the therapist population or even the sample of therapists used in a particular study.²

Discussion

Several counterarguments to the one presented here can be raised. Perhaps the most persuasive is that therapists in psychotherapy studies are not in fact chosen in a purely random manner from a defined population and that the therapist factor must therefore be conservatively considered as fixed. In reality, regarding therapists as fixed is not conservative at all, since it is generally much easier to obtain statistically significant results if the therapist factor is treated as fixed. Even if the researcher is scrupulous in pointing out that this factor is being considered as fixed and that results should not be generalized across therapists, the very fact that the results have been published strongly implies that they are believed to be of some generality.

Another objection would be that these criticisms could just as well be leveled at psychology experiments in general, that to ask psychotherapy researchers to include therapists in their designs is no more reasonable than to ask experimental psychologists to include experimenters in theirs. Actually, this is not a bad idea. Hopefully, experimentalists who use several experimenters do in fact assess the reliability of their results across experimenters either by including them in preliminary analyses or by some less

² Virtually all recent psychotherapy research has handled therapists in one or the other of these inappropriate manners. To get some idea of the pervasiveness of these design problems, the 1975 issues of the *Journal of Consulting and Clinical Psychology* and the 1973 and 1974 issues of the *Journal of Abnormal Psychology* were surveyed. Brief reports and articles with $n = 1$ were excluded. The search yielded 33 articles reporting the application of analysis of variance to results of studies of psychotherapy or related techniques such as interviewing, counseling, and behavior modification. In only 1 of these was the therapist factor treated as random. It can be inferred from reported degrees of freedom that the therapist factor was treated as fixed in 3 of the studies. Therapist effects were inappropriately ruled out (by, e.g., failing to test all effects needed for error terms or using either $\alpha < .20$ or unspecified α in preliminary tests) in 8 of the studies. The therapist factor was ignored in the analyses of variance reported in the remaining 21 articles.

formal procedure. This becomes important to the extent that the experimenter's role goes beyond that of a passive observer. Be this as it may, it is hopefully the case that experimenters are usually not explicitly included in analyses, in that their effects are negligible and their presence would merely clutter the presentation. The point is not that every conceivable factor should be included in analyses of variance but merely that factors of generally agreed-upon substantive importance should be included.

Another argument that can be quickly disposed of is that the results of psychotherapy studies do in fact replicate well. In this view, the theoretical problem of lack of generality is compensated for by the empirical fact of repeated replication. One may consult the appendix to the review by Luborsky, Chandler, Auerbach, Cohen, and Bachrach (1971) to see the fallacy of this argument. With few exceptions, there is unimpressive consistency in findings concerning the same hypothesis. Ultimately, the reliability of any phenomenon is demonstrated by repeated independent replications. The p values attached to F ratios serve to give other researchers some idea as to whether attempts at replication would probably be successful. Viewed from this perspective, p values derived from analyses of variance in which the therapist factor is fixed are grossly misleading.

A random factor is actually defined by two attributes: (a) its levels are sampled, and (b) this sampling is done at random. What does one do if levels of the therapist factor have been sampled but the sampling was not random? The conventional advice is that if levels of a factor are not sampled randomly, then the factor must be regarded as fixed. But this advice is given in the hope that if a sampled factor were so regarded, no credence to the generality of the results would be given.

Given that one must regard therapists as a random factor if a study is to have any scientific value, is there any justification for doing so? Actually, the same reasons used to treat subjects/patients as a random factor may sometimes support the treatment of therapists as a random factor. The implicit assumption that allows treatment of subjects as a random factor even if they were not randomly sampled is that random "presampling" has occurred. That is, the forces that brought the particular subjects into contiguity with the investigator were random with respect to the experiment in question. The same line of reasoning could, within reason, be applied to experimenters or therapists. I do not mean to imply that "two wrongs make a right"

or that one should not make every effort at random sampling of therapists. I have merely tried to outline a rationale for arguing that some studies analyzed with the therapist factor as fixed could legitimately be reanalyzed with this factor considered as random rather than being discounted completely.

To what extent do the criticisms discussed in this comment invalidate published psychotherapy research that has been inappropriately analyzed? Unless treatment F s can be recomputed—and this is seldom possible—in studies that have treated the therapist factor as fixed or have ignored it altogether, there is good reason to be wary of generalizations based on them. As the reanalyses described above demonstrate, treating the therapist factor as random rather than as fixed can have drastic effects on the significance of F values. Effects originally reported as significant at the .01 and .001 levels may be reduced to nonsignificant levels by this change in analysis. Given this, it is quite likely that the published research on psychotherapy contains an extremely high proportion of Type I errors. We know, then, a lot less about psychotherapy than we thought we did.

Resurrection of Uniformity Assumption Myths and the Fallacy of Statistical Absolutes in Psychotherapy Research

Gordon L. Paul and Mark H. Licht
University of Illinois at Urbana-Champaign

Martindale's assertions are criticized for failure to recognize the lack of uniformity in domains and classes of variables involved in psychotherapy research, and the need to fit design and analyses to the data obtained and the questions asked. Fallacies regarding absolute or invariant use of statistical models and techniques are discussed. Included are inappropriate statistical bases for generalization, confusion in the contribution of statistical analyses to internal versus external validity, and misapplication of statistical procedures—particularly "therapists as random effects" for most psychotherapy research. Systematic accumulation of knowledge from psychotherapy research will more likely come from adequate specification of classes of variables and focused experimental questions, combined with thoughtful design and tactics, not from rigid application of textbook statistical models to areas in which they do not fit.

Kiesler (1966) drew attention to the "uniformity assumption myths" that had historically plagued research in psychotherapy. Nearly all classes of variables of interest in psychotherapy research are more heterogeneous than our short-hand descriptive labels suggest. Failing to recognize such heterogeneity resulted in neither independent nor dependent variables being adequately considered and in overgeneralizations from inadequately specified data. Recent articles give evidence that these myths of uniformity are being resurrected (e.g., Martindale, 1978; Smith & Glass, 1977; Mariotto, in press). Martindale resurrects uniformity assumption myths through assertions that results of psychotherapy research should be generalized to psychotherapy, patients, and therapists "in general"—a focus on questions known not to be fruitful for over a decade. He further extends inappropriate assumptions of uniformity to statistical "absolutes," which are asserted as requirements for research in psychotherapy.

Complexity of Variables in the Research Enterprise

Before addressing Martindale's (1978) fallacious assumptions (space limitations prohibit

discussion of his points with which we agree), a brief reminder of the complexity of variables and the nature of the psychotherapy research enterprise may aid in orientation. These issues are developed and described in detail along with recommended designs and tactics by Paul (1969).

Other than the greater number and complexity of variables involved, the principles and methods required for psychotherapy research appear to be no different than those of any other area. Because the knowledge obtained in psychotherapy research should ultimately find its way to clinical practice, both internal and external validity become especially important (Campbell & Stanley, 1966). Internal validity refers to the degree to which plausible rival hypotheses have been ruled out within a study. Without internal validity, a study is uninterpretable. There is really only one principle for establishing internal validity—Ask a question in such a way that enough controls can be introduced to unambiguously evaluate the effects of independent variables. External validity refers to generalizability beyond the specific study. Unlike internal validity, external validity can be established only by additional investigation.

Because of the lack of uniformity of labeled clients, therapists, or treatments, any study of psychotherapy should include descriptive, measurement, or control operations for each of several detailed classes of variables to establish internal validity and provide hypotheses regard-

Requests for reprints should be sent to Gordon L. Paul, Psychological Clinic, University of Illinois, Champaign, Illinois 61820.

ing external validity—hypotheses that can later be subjected to empirical test. Within the client domain, these classes of variables include (a) the clients' distressing behaviors that are the focus of treatment; (b) the clients' relatively stable personal-social characteristics; and (c) the clients' physical-social life environment. Within the therapist domain, these classes of variables include (a) the specific therapeutic techniques through which change in problem behaviors is attempted; (b) the therapists' relatively stable personal-social characteristics; and (c) the physical-social treatment environment. The third major domain, time, serves to further specify the set of circumstances for other classes of variables and to determine the focus and nature of assessments needed within and between periods related to treatment, dependent on the questions asked.

Paul (1969) proposed the ultimate questions to be answered in clinical research (including psychotherapy) as: "What treatment, by whom, is most effective for this individual with that specific problem, under which set of circumstances, and how does it come about?" (p. 44). Although no single study can ever answer these questions, specification of the aspect of the question for which answers are sought, combined with adequate description, measurement, or control of each of the classes of variables, allows stronger internal validity and meaningful accumulation of knowledge across studies. The means of obtaining answers or partial answers then becomes a question of design and tactics.

Fallacies of Statistical Absolutes

With the above reminders of the complexity of variables in the enterprise, let us turn specifically to Martindale's (1978) more troublesome assumptions and assertions. These fall into two groups: absolutes that fail to reflect reality and absolutes that inappropriately assume uniformity of design and analyses.

Absolutes That Fail to Reflect Reality

The majority of Martindale's (1978) assumptions that fail to reflect reality are mirrored in his assertion that "to treat the therapist factor as fixed rather than random . . . completely destroys the scientific value of the study, since all conclusions must be restricted to the particular therapists used in the study" (p. 1528). Reflected in this assertion is the assumption that the only justification for generalizing is random sampling, as well as a confusion concerning the contribu-

tion of statistical analyses to internal versus external validity in an experimental study. Campbell and Stanley (1966) noted the "reluctance to accept Hume's truism that *induction or generalization is never fully justified logically*" (p. 17). Unlike random sampling in survey research in which the logic of probability statistics provides justification for extrapolation of sample findings to a defined population, the focus of randomization in experimental research is nearly always on internal validity, not representativeness of the sample. Contrary to Martindale's assumptions, calling a factor or levels of a factor "random" in an investigation of psychotherapy does not make it so. Such a practice is likely to be misleading, in that others may assume statistical justification for extrapolation on inappropriate grounds, resulting in overgeneralization of findings from less powerful analyses.

The "scientific value" of a study can only be determined by multiple criteria. Scientifically meaningful *conclusions* from a particular study are dependent on the internal validity of the experimental operations—the degree to which plausible rival hypotheses have been ruled out of cause-effect relationships in that study. The generality or external validity of findings in psychotherapy research, in practice, can seldom be more than a rational-empirical undertaking, rather than a statistical one. Hypotheses concerning the generalizability of findings are, thus, strengthened to the extent that a study provides strong internal validity and thorough measurement or description of the relevant domains and classes of variables over which generalization might be expected on the basis of knowledge obtained from other sources. Conventional interpretations in the majority of texts on statistical design point out that generalization of findings from "fixed factors" should only be within the *levels* actually included in a study. With regard to therapists as a fixed factor, this would refer to therapists with similar characteristics—not just the particular therapists involved any more than conclusions would be restricted to the particular settings, instruments, times, and so forth, involved in a specific study. However, such generalizations remain hypotheses until extensions and limitations on the conditions in which findings hold are empirically tested—a problem in experimental design and tactics, not statistical models (see Paul, 1969).

Absolutes That Inappropriately Assume Uniformity of Design and Analyses

Several of Martindale's (1978) assumptions and assertions could be appropriate for a specific

experimental question regarding psychotherapy, but they appear patently inappropriate for other questions—in fact, for most questions that investigators might rationally approach. Abstracting from Martindale's comment, these include assertions that both therapists and clients must be randomly selected for experimental inclusion; treating therapists as a fixed effect in analyses of variance drastically inflates the possibility of Type I errors; the number of therapists rather than the number of clients determines the degrees of freedom and power of statistical tests; and the only way to increase the power of hypothesis testing is to increase the number of therapists included.

Not only do the above assertions reflect the myth of uniformity of therapists and clients in general, but they also extend the myth to experimental design and analyses requirements as well. As with any other area of scientific research, investigations of psychotherapy must fit the design to the questions, or aspects, of the ultimate clinical research question asked. Asserting requirements as absolutes, irrespective of the purpose of an investigation or of the purpose of a particular set of analyses can only perpetuate a "cookbook" approach that fails to recognize that statistics are only tools to aid in decision making—They cannot replace thought or careful experimental design and controls.

Martindale (1978) provides a prime example of the outcome of such a cookbook approach in his selection of data for reanalysis from Paul (1966). He asks, "What would happen to the F s if we were willing to believe that therapists were selected at random?" (p. 1528) (a *totally* unwarranted assumption) and recomputes F s treating the therapist factor as a "random effect." In fact, such an analysis would have been *inappropriate* for the data selected *even if* the therapists had really been "randomly sampled," since the major purpose of those particular data analyses was to investigate the therapist ratings to identify possible limiting conditions on the validity of treatment effects previously evaluated by objective, external means. Maximum power within reasonable assumptions would logically call for fixed effects handling of that data, no matter how therapists came to participate in the study.

Martindale (1978) also implies that reliability of therapist contributions cannot be assessed if of therapist contributions cannot be assessed if treated as fixed effects, and that p values associated with F ratios reflect the probability of replication. Elementary considerations of experimental design and statistical inference are, in fact, discussed in most texts on the subject.

However, it seems worthwhile to note that p values are dependent on N and have no reflection on practical or scientific "significance"—They merely indicate the believeability that a difference in a particular direction was obtained. They tell nothing about the probability of replicating a difference of that size again—with the same or different subjects, whether in a fixed or a random model. The reliability and strength of effects for either fixed or random factors in analyses of variance can be examined—not by p s but by correlational analyses and such statistics as coefficient alpha (Winer, 1971) and epsilon-squared (Peters & VanVoorhis, 1940).

Conclusion

The need to abandon uniformity assumption myths is no less now than when Kiesler (1966) originally summarized them. Rather than therapists and clients in general, adequate descriptive, measurement, and control operations focused on the *specific* domains and classes of variables detailed by Paul (1969) appear necessary for establishing the internal validity of a given study and for aiding in rational generalization to practice and further investigations. The failure to replicate findings in psychotherapy research is more likely a function of inappropriate attempts to generalize without recognition of the myths of uniformity than of the error terms selected in a particular analysis. The fallacy of statistical absolutes is equally worthy of abandonment if we are to progress systematically in accumulation of knowledge. Neither a "box score" approach to determining treatment effects over studies without adequate representation of their internal validity or the internal purpose of measurement (e.g., Smith & Glass, 1977), nor absolutes in requirements of design and analyses (e.g., Martindale, 1978) add clarification—no matter how sophisticated the mathematics involved. We find ourselves in strong agreement with Myers (1972) that "in practice we expect the experimenter to use his brains as well as his F ratios to draw inferences" (p. 169).

A Question as to the Validity of the Verbal Scale IQ as a WAIS Short Form

William M. Reynolds

State University of New York at Albany

Wildman and Wildman's contention as to the validity of the Verbal Scale IQ as a Wechsler Adult Intelligence Scale short form is shown to be based on an inappropriate analysis of their data. Upon reanalysis, the claim for validity is unsupported on the basis of original criteria. Results are presented that also fail to support the validity of the Verbal IQ as a short form measure.

The development of short forms of standardized intelligence tests has been of concern to both researchers and clinicians. Due to their differential component structure, the Wechsler tests have been the subject of many dissections into the short-form status (Finch, Childress & Ollendick, 1974; Levy, 1968; Luszki, Schultz, Laywell, & Dawes, 1970; Silverstein, 1970). Recently Wildman and Wildman (1977) reported results that they contend support the validity of using the Verbal IQ as a short form of the Wechsler Adult Intelligence Scale (WAIS; Wechsler, 1955). They cite three criteria, originally proposed by Resnick and Entin (1971), as necessary for the validation of a short-form test: (a) There should be a significant positive correlation between the short form and the standard test form; (b) the obtained score means between the two forms should not be statistically different; and (c) there should be a high degree of concordance between forms on the IQ classification level assigned to examinees.

Wildman and Wildman (1977) found (a) a product-moment correlation of .97 between Verbal Scale IQ and Full Scale IQ ($n = 100$), (b) a t -test value of .95 ($p > .05$) between test form means, and (c) a change in diagnosis of mental retardation in 13% of the cases. They concluded from their data that the Verbal Scale IQ meets the above stated criteria and therefore is a valid short form for the WAIS Full Scale IQ. A re-examination of their data, however, disputes this conclusion. Besides the fact that as McNemar (1949) pointed out, a spurious correlation will result when a subscore that is part of

the total score is correlated with the total score, Wildman and Wildman tested the significance between the means of the Verbal Scale IQ and the Full Scale IQ via a t test for independent samples. The inappropriate use of independent samples t tests with high positively correlated dependent samples will, as Glass and Stanley (1970) pointed out, result in an overestimation of the standard error of the differences between the means, subsequently resulting in nonsignificant differences where significant differences between the two means exist. If for related measures,

$$t = \frac{\bar{D}}{\sqrt{\frac{S_1^2 + S_2^2 - 2r_{12}S_1S_2}{N}}}$$

where \bar{D} is the mean difference, S^2 is the variance, r is the correlation coefficient, and N is the sample size, is used to reanalyze Wildman and Wildman's results, a t of 5.46 ($p < .001$) is obtained, which is highly disparate from the t value originally determined. One would therefore reject the validity of the Verbal Scale short form.

To check the possibility that the above results could in part be due to heterogeneity of Wildman and Wildman's (1977) sample (psychotics, brain damaged, and normals), WAIS results from 42 normal adults, ranging in age from 20 to 65 years with a mean age of 30.46 years ($SD = 12.70$), were analyzed. The mean Verbal Scale IQ of this group was 120.00 ($SD = 11.37$), and the mean Full Scale IQ was 117.71 ($SD = 10.61$). The IQ ranges were 87-141 for the Verbal Scale and 89-134 for the Full Scale. The obtained product-moment correlation (uncorrected) between the Verbal and Full Scale IQs was .92 ($p < .01$). A t test for correlated mea-

tures between the means of the Verbal Scale and Full Scale IQs produced a t of 3.33 ($p < .01$).

The results of this study also fail to support the contention of the Verbal Scale IQ as a valid WAIS short form when nonsignificant differences between test form means are used as a criterion.

Validity of the Verbal Scale IQ as a WAIS Short Form: A Reply to Reynolds

Robert W. Wildman and Robert W. Wildman II
Central State Hospital, Milledgeville, Georgia

We were criticized because of our use of improper statistics in supporting the validity of the Wechsler Adult Intelligence Scale Verbal IQ as a short form of the Full Scale IQ. We agree with Reynolds that we erred in the choice of one statistical test. However, we contend that from a practical standpoint, the use of the Verbal IQ as a short form had considerable value as a screening device and should not be discarded because of this one criticism.

We (Wildman & Wildman, 1977) presented data interpreted as being supportive of the validity of the Wechsler Adult Intelligence Scale (WAIS) Verbal IQ as a short form of the Full Scale IQ. Resnick and Entin's (1971) three criteria for evaluating the validity of the short form were used in the 1977 study: (a) There had to be a significant positive correlation between the short form and the standard test form; (b) the obtained score means between the two forms should not be statistically different; and (c) there should be a high degree of concordance between forms on the IQ classification level assigned to examinees.

It was decided to use the t test for unmatched samples because one could make either of two assumptions—that the samples were similar or dissimilar. At the time the decision was made, we felt that we did not want to make the *a priori* assumption that our short form using the Verbal Scale would be a valid short form and predict the Full Scale IQ. We thought that this was a biased alternative to choose and neglected to think through the fact that we were using the same sample of subjects and the difference this would make statistically in testing the second criterion mentioned above. We agree with Reynolds (1978) that a matched-sample t test would have certainly been the logical one to use.

The Verbal Scale of the WAIS has a very significant positive correlation with the Full Scale IQ, and there is a high degree of agree-

ment regarding the IQ classification levels assigned to the subjects. We might say that "two out of three ain't bad." Even though the Verbal Scale short form did not meet the second criterion of Resnick and Entin (1971), from a practical standpoint the main point of a short form is to save time and to classify individuals accurately, which then makes it of value as a screening device in many clinical situations. Reynolds' data with 42 normal adults indicate a high correlation between the Verbal and Full Scale IQ. However, Reynolds fails to mention how many subjects would have been misclassified by placing them in Wechsler IQ categories.

In short, Reynolds' criticism was correct, but it seems that the Verbal Scale should be accepted as a good short form because of its demonstrated clinical value rather than discarded because it failed on one of the three criteria proposed in one article.

Brief Reports

Effects of Type of Social Reinforcement on the Intelligence Test Performance of Lower-Class Black Children

Francis Terrell, Jerome Taylor, and Sandra L. Terrell
University of Pittsburgh

This study examined the effects of different types of reinforcement on the performance of black males on the Wechsler Intelligence Scale for Children-Revised. After each correct response, participants were given either no reinforcement, a candy reward, traditional social reinforcement, or culturally relevant social reinforcement. Children given candy or culturally relevant social reinforcement obtained significantly higher scores than children given either no reinforcement or traditional social reinforcement.

A somewhat consistent finding is that lower-class black children perform better on cognitive tasks when given tangible rewards as opposed to social reinforcers (Schultz & Sherman, 1976). Typically, social reinforcers have consisted of such verbalizations as "good" and "fine." A problem with these studies is that little attention has been given to the type of social reinforcers used. In view of the different value system among blacks (Terrell & Taylor, Note 1), it is possible that appropriate social reinforcers have not been used in previous studies. This study explored the effects of culturally relevant reinforcers on lower-class black children's performance on the Wechsler Intelligence Scale for Children-Revised (WISC-R).

Participants were 80 lower-class second-grade black children selected from a southern urban area and randomly assigned to either a nonreinforcement condition, a candy reward condition, a social reward condition, or a culturally relevant social reward condition. All children were then individually administered the short form of the WISC-R (Silverstein, 1967) by the first author, a black PhD psychologist. In the nonreinforcement condition, the children were given no reward; in the candy reward condition, chil-

dren were given an M&M after each correct response; in the social reward condition, children were given verbal praise such as good and fine after each correct response; and in the culturally relevant condition, children were given verbal praise such as "good job, blood" and "nice job, little brother" after each correct response. Scoring was done by an experienced master's level clinician who was unfamiliar with the participants and purposes of this study.

Children in the control group obtained a mean IQ score of 81.55 ($SD = 9.88$); the social reward group obtained a mean IQ score of 84.85 ($SD = 12.17$); the tangible reinforcer group obtained a mean IQ score of 92.85 ($SD = 11.39$); and the culturally relevant group obtained a mean score of 99.15 ($SD = 10.49$). Significant differences were found among the groups, $F(3, 76) = 10.37$, $p < .01$. Using Scheffé's method of post hoc comparisons, no significant differences were found between the control and social reinforcement groups. Also, no significant differences were found between the tangible and social reinforcement groups. However, children given tangible reinforcement had significantly higher mean IQ scores than children in the control group ($p < .05$). Further, children given culturally relevant rewards obtained significantly higher IQ scores than children in the control group ($p < .01$) and children in the social reinforcement group ($p < .01$).

Thus, it is suggested that the type of social reinforcer has an important effect on black children's performance on cognitive tests. Indeed, the results suggest that the use of appropriate

The Child With Cancer: Patterns of Communication and Denial

John J. Spinetta and Lorrie J. Maloney
San Diego State University

What role do communication and denial play in the coping efforts of children with cancer? Although no conclusions are drawn regarding cause-effect relationships, results indicate that the level of family communication about the illness, as expressed in the mother's judgment of communication, is correlated with three of the four hypothesized responses in the child. The study demonstrates the usefulness of three instruments as effective tools in measuring the child's reactions to the illness. Several questions are raised as possible avenues for further cross-sectional and longitudinal research on the communication hypothesis with the use of the instruments.

If it is true that a child with cancer as young as 6 years of age is aware of the serious nature of the illness (Bluebond-Langner, 1977; Spinetta, 1974), what does the child do with this knowledge and awareness? Does the child communicate with the parents about the prognosis in an effort to seek emotional support or does the child live in silence with the knowledge? The present study is a pilot effort to test instruments that might help clarify the issue.

To delimit the term *coping* and make it operational for the study, the following behaviors in the 6- to 10-year-old child were defined as successful attempts on the part of the child to master troublesome situations relative to the illness: a nondefensive personal posture, closeness to parental figures, happiness with oneself, and the freedom to express negative feelings within the family. Basic to this view of effective coping is our assumption that communication of a child's thoughts and concerns, both happy and painful, is both a healthier state of mental well-being and a prerequisite to family support than retaining thoughts in silence (Spinetta, 1977). It was hypothesized that a child whose family allows discussion of the illness and its prognosis would be able to cope more effectively with the illness. Specifically, the child whose family indicates open channels of communication regarding the illness would (a) score as less defensive on a scale of defensiveness (Sarason, Davidson, Lighthall, Waite, & Rue-

bush, 1960); (b) express closeness to family members, as measured by an interpersonal distance scale (Spinetta, Rigler, & Karon, 1974); (c) express happiness with self, as measured by messages to self in the Family Relations Test (Anthony & Bene, 1957); and (d) feel free to express negative feelings within the family, as measured by the Family Relations Test.

Levels of openness within the family regarding communication about the illness were measured by a questionnaire filled out by the mother. Five items, each scaled 1-4, questioned the mother's view of (a) how much the patient-child knows about the illness, (b) what kinds of questions the child asks, (c) how the parent responds to the questions, (d) what kinds of questions the siblings ask, and (e) how the parent responds to the siblings' questions. The total score of the combined categories represents the level of communication within the family, with the highest score indicating the fullest levels of communication. The study was envisioned as an effort to see whether there is a correlation among the variables; it was not intended to demonstrate a cause-effect relationship. The subjects of the study were 16 children aged 6-10 years with a diagnosis of leukemia who were being treated in outpatient clinics in three local children's facilities (Spinetta & Maloney, 1975).

Results are as follows: Using the level of communication within the family as a criterion measure regarding the illness, its prognosis, and treatment, five predictors were subjected to a multiple regression analysis, as summarized in Table 1. Three of the predictors contributed significantly to the amount of variance explained, yielding a multiple correlation of .71. Defense was the strongest predictor, followed by per-

This study was supported in part by a grant-in-aid to the first author from the San Diego State University Foundation.

Requests for reprints should be sent to John J. Spinetta, Department of Psychology, San Diego State University, San Diego, California 92182.

sonal space difference—father and negative self. These three predictors supported three of the four hypotheses.

The data were then analyzed by a multivariate analysis of variance using the same variables, with families divided into communicative (above the median, $n = 7$) or quasi-communicative (at or below the median, $n = 9$). Results are summarized in Table 2. The combination of variables significantly differentiated the communicative from the quasi-communicative families ($p < .038$). The multivariate analysis of variance supports the first three hypotheses in the predicted direction.

Although no conclusions can be drawn regarding cause-effect relationships, results indicate that the level of family communication about the illness, as expressed in the mother's judgment of communication, is related to coping strategies in the child. Families in which levels of communication about the illness are high are those families in which the children (a) exhibit a nondefensive personal posture, (b) express a long-range close relationship with the parents, and (c) express a basic satisfaction with self. Freedom to express negative feelings openly within the family was not significantly correlated with level of communication. Further studies of a longitudinal and interventional nature with the use of the above instruments are needed to test whether in fact there is a cause-effect relationship, that is, whether openness in levels of family communication regarding the illness leads to closer family ties and to healthier coping responses in the child.

Further studies from multiple sources are also needed to clarify whether in fact the mother's judgment of openness is a valid judgment of the true situation; whether there is a difference in communication patterns as the children go through subsequent relapses; whether parents become more or less communicative regarding implications of the illness as the child nears death; and, above all, whether families differ

Table 2

^a $df = 1, 13$.

^b Higher score represents desire to have parents closer.

in the level of openness that their support mechanisms can tolerate.

If one of the goals of work with children with cancer is to give them access to the intra-familial sources of support that they need most to help them in their struggle, then the present effort pointing to the relationship between levels of communication and the life-threatening child's adaptive strategies is a step toward that goal.

Kenneth L. Ozmon

University of Prince Edward Island
Charlottetown, Canada

This study examined the relationship between repression-sensitization (R-S) and visits to a prison infirmary for males during a 1-year period. The main effect for the R-S dimension was significant for (a) total number of visits, (b) number of medically justified visits, and (c) number of medically unjustified visits. In each instance, sensitizers had significantly more visits than repressors. Sensitizers and repressors did not differ in the proportion of justified/unjustified visits. Differences found between repressors and sensitizers in total visits were attributed to differences in the incidence of actual illness.

Bell and Byrne (1978) have suggested that repression-sensitization (R-S) may be related to health behavior. The theoretical basis for such a relationship stems from developments in psychosomatic medicine that suggest a strong relationship between illness behavior and coping style. To the extent that the R-S dimension reflects characteristic ways of coping with stress, one might expect repressors and sensitizers to differ in terms of health behavior. Byrne, Steinberg, and Schwartz (1968) reported that sensitizers indicated a greater frequency and/or severity of illness than repressors and that male sensitizers sought medical help significantly more frequently than did male repressors. One way of accounting for these differences is to hypothesize differences in perceptions concerning illness and in the typical response to illness made by repressors and sensitizers. Sensitizers, because of their excessive use of sensitizing-type behaviors in the presence of anxiety-arousing stimuli, may have significantly higher subjective estimates of their chances of contracting an illness. This would lead to an increased likelihood of engaging in specific health behaviors. Gayton, Ozmon, Bassett, and Tavormina (1976) found that sensitizers had significantly higher perceived vulnerability-to-illness scores than did either repressors or intermediates.

An alternative hypothesis would be to assume physiological differences that lead sensitizers to be more susceptible to illness. If this were the case, the higher frequency of health visits on the part of sensitizers would be related to an increased incidence of actual disease. One way of clarifying these two hypotheses would be to divide the total number of visits to a health facility into justified visits (i.e., when medical attention was required) and unjustified visits (i.e., when no medical attention was deemed necessary). If physiological differences existed, we would expect sensitizers to have significantly more medically justified visits than repressors. If the differences were strictly at the level of perceived vulnerability, we would expect sensitizers to have significantly more unjustified visits with no differences in terms of medically justified visits.

Method

The records of all inmates who had been given the Minnesota Multiphasic Personality Inventory (MMPI) during the years 1973-1974 were taken from the files of the psychodiagnostic center of a prison for adult males in western Tennessee. The selection criteria yielded 392 protocols that were scored with templates made from the Byrne Revised Repression-Sensitization Scale (Byrne, Barry, & Nelson, 1963). Three groups of 30 subjects each—repressors, intermediates, and sensitizers—were selected from the distribution on the basis of their R-S scores. The groups did not differ in terms of

Repressors	19.13	4.49	9.10	7.83	5.03	3.70	4.07	5.75
Intermediates	50.23	1.92	25.93	17.10	10.43	6.93	15.50	12.54
Sensitizers	78.50	8.50	48.13	26.56	17.90	11.68	30.23	21.53

* R-S = repression-sensitization.

age ($F < 1$) or education ($F < 1$). A measure of health behavior was obtained by recording from the prison medical records the number of sick-call visits made by each inmate in the study during a 1-year period. The number of opportunities to report voluntarily for sick call was equal for all inmates in the study. A record was also made concerning whether the prison medical officer found the inmate in need of medication and/or treatment during the dispensary visit. When this was the case, the visit was counted as medically justified. When there was no indication of medication and/or treatment, the visit was counted as medically unjustified.

Results and Discussion

Table 1 presents the means and standard deviations for the three groups on the R-S scale and the three dependent measures: (a) total number of sick-call visits; (b) number of justified sick-call visits; and (c) number of unjustified sick-call visits. A one-way analysis of variance was used to examine the relationship between each dependent variable and the R-S dimension.

Results of the three analyses indicated significant F ratios on each of the dependent measures: (a) number of sick-call visits, $F(2, 87) = 32.57$, $p < .001$; (b) number of medically justified visits, $F(2, 87) = 18.96$, $p < .001$; and (c) number of medically unjustified visits, $F(2, 87) = 23.70$, $p < .001$.

Multiple post hoc comparisons of the group means were made using the Scheffé (1953) procedure. Examination of the total number of sick-call visits revealed that sensitizers made significantly ($p < .01$) more trips to the prison dispensary than either intermediates or repressors. In turn, intermediates made significantly ($p < .01$) more trips than repressors. Examination of the frequency of justified visits revealed that

sensitizers made significantly ($p < .01$) more of these visits than did either intermediates or repressors. The latter two groups did not differ significantly from one another on this measure. Examination of the frequency of unjustified visits indicated that sensitizers made significantly ($p < .01$) more of these visits than did either intermediates or repressors. The latter two groups did not differ significantly from one another on this dimension.

The present study supports the Byrne et al. (1968) finding that male sensitizers seek medical attention significantly more frequently than do male repressors. Our previous analyses did not allow us to determine whether differences between repressors and sensitizers were due to differences in susceptibility to illness, perceived vulnerability to illness, or both. In order to help choose between the two alternatives, a post hoc analysis of variance was performed on the proportion of justified/unjustified visits. The mean proportion for repressors was 1.79; intermediates, 1.05; and sensitizers, 1.61. Results of this analysis, $F(2, 87) = .94$, ns , indicate that sensitizers and repressors do not differ in the proportion of justified/unjustified visits. This indicates that the differences found between repressors and sensitizers in total visits were most likely due to differences in actual illness.

Other possible explanations remain. Repressors may ignore or deny physical symptoms and avoid visiting a health facility even when they are actually ill. If this possibility were correct, the results of this study would be interpreted quite differently. Further research on the relationship between repression-sensitization and health behavior would seem warranted.

Relationship of Two Process Measurement Systems for Group Therapy

John E. Roe and Keith J. Edwards

Rosemead Graduate School of Professional Psychology
Biola College, LaMirada, California

Ten-minute audiotapes from 42 group therapy sessions were rated using four Hill interaction matrix variables and the Truax-Carkhuff variables of empathy, immediacy, self-exploration, and confrontation. Canonical correlation analysis suggested that the two systems converged along a dimension labeled *initiating skills*. A factor analysis suggested three underlying factors of group process labeled *Initiating Skills*, *Responding Skills*, and *Discussion Skills*. Factors 1 and 3 suggest a multidimensional structure of immediacy clarified by the Hill variables. Factor 2, with high loadings on empathy and self-exploration, identified a qualitative dimension of group process not tapped by the Hill matrix.

Research on the psychotherapeutic process has produced a proliferation of process measurement systems from many diverse perspectives. Kiesler (1973) reported more than 27 direct process measures based on observations of therapy sessions and an additional 25 indirect measures. The use of process measures has been productive in identifying factors in therapy that relate to improvement (Carkhuff & Berenson, 1967). However, theoretical integration of the results from process research has been difficult, since the studies range in disorganized fashion over the entire field of psychotherapy (Meltzoff & Kornreich, 1970). Research is needed that investigates the potential convergent validity of process measurement systems that have empirically demonstrated utility. Understanding the communality among systems of measurement is essential to integrating the theories on which they are based. The purpose of the present study was to investigate the convergent validity of two systems for assessing group process, the Hill interaction matrix (Hill, 1971) and the Truax-Carkhuff (1966) dimensions of facilitative functioning.

The group process measurement system developed by Truax and Carkhuff contains the variables of empathy, immediacy, self-exploration, and confrontation. These dimensions are well-known. Detailed definitions can be found in Truax and Carkhuff (1966). The second system of process measurement investigated was Hill's interaction matrix (Hill, 1967). As used in the present study, the Hill matrix involved a 2×2

fourfold classification modeled after the work of Lewis and Mider (1973). The first dimension defines the content style of the group interaction, with the two categories being topic-centered and member-centered styles. Interactions are classified on this dimension by asking the question, "What are the group members talking about—topics (there and then) or one another? (here and now)." The second dimension is a work-style dimension. The term *work* refers to the participation of members in the roles of patient and therapist with the goal of self-understanding. The two categories on the work-style dimension are simply *prework* and *work*.

Group process interaction segments were taken from 11 therapy groups of ministers and their spouses involved in a month-long training seminar in pastoral counseling. Groups were led by experienced counselors with graduate students as coleaders. Each group consisted of approximately 10-12 persons. Empathy, immediacy, self-exploration, and confrontation were rated using $\frac{1}{2}$ -point discriminations on 5-point scales. A modification of the Hill Interaction matrix (Form G) was used to assess the group interactions. The Hill matrix variables were evaluated by means of a 32-item questionnaire that required the raters to estimate the percentage of time spent on interactions represented by the four variables (a) topic-centered prework, (b) topic-centered work, (c) member-centered prework, and (d) member-centered work.

The unit of measurement was a 10-minute audiotape taken from the midpoint of each 90-minute session. Each group was taped during the second, fourth, sixth, and eighth sessions. A total of 42 10-minute segments were placed

Table 1
Canonical Variable Loadings

HIM-G				Truax-Carkhuff			
1	2	3	4	E	I	SE	C
.348	.493	-.266	.768	.206	.994	.056	.430

Note. HIM-G = Hill interaction matrix, Form G; E = empathy, I = immediacy; SE = self-exploration, and C = confrontation.

in random order on a master tape. The tapes were evaluated by four raters who were experts in the ratings of the systems used. Two raters evaluated the tapes using the Truax-Carkhuff variables. Correlations between the ratings given by the two raters were .79 (empathy), .93 (immediacy), .72 (self-exploration), and .87 (confrontation). Two other raters rated the 42 segments using the Hill matrix. The raters' quadrant scores correlated .91 (topic-centered prework), .97 (topic-centered work), .89 (member-centered prework), .94 (member-centered work). The use of independent sets of expert raters to evaluate the group interactions is considered a major strength of the present study. Communitality between the two systems of measurement was examined using canonical correlation analysis. The multivariate structure of the eight process measures was investigated using factor analysis.

Only the first canonical correlation ($r_c = .58$) was statistically significant, $\chi^2(16) = 28.5$, 16, $p = .03$. There was .339 shared variance between the two sets of variable. The first canonical variate, given in Table 1, shows the highest loadings for topic-centered work, member-centered work, immediacy, and confrontation.

The results of the factor analysis expanded the findings. Factor loadings for the first factor parallel the structure of the canonical variate with loadings on member-centered work (.86), immediacy (.63), and confrontation (.72). The second factor consisted of empathy (.91) and self-exploration (.91), and the third factor was defined by the variables topic-centered prework (.75), topic-centered work (.89), and immediacy (.51). All other loadings were below .25.

The first canonical variable suggests overlap of the two process systems on a single dimension, which could be termed *initiating skill*. The Truax and Carkhuff variables involved are action oriented, having a here-and-now emphasis that parallels Hill's concept of work in which group members assume the roles of helpers. The factor analysis sheds more light on the structure of the eight process variables as a group. Factor 1 was the interbattery factor. The second

factor encompasses the facilitative responding skills of Truax and Carkhuff. The third factor appears to be related to discussion skills. The multivariate nature of the relationships among these process measures supports Carkhuff's view that effective interpersonal process involves both responding and initiating. It was expected that empathy and self-exploration would be more highly correlated with member-centered work than they were, based on Hill's position that Quadrant 4 has the highest therapeutic value. However, the results show an independence of these variables. The important concepts of empathy and self-exploration are not accounted for by Hill's variables. It appears that while Hill's Quadrant 4 identifies the conceptually important here-and-now character of group process, assessment of whether the interaction is facilitating or detracting is not possible.

When considered together, the two process systems complement and enhance each other. Hill's system shows that immediacy as conceptualized by Truax and Carkhuff is multidimensional, involving both topic-centered and member-centered interactions. The empathy and self-exploration variables of Truax and Carkhuff suggest a qualitative dimension not explicit in the Hill schema. Further research on the development of a system that incorporates both aspects holds promise for enhancing our understanding of group therapy.

Development and Validation of a Heterosocial Skills Inventory: The Survey of Heterosexual Interactions for Females

Carolyn L. Williams and Anthony R. Ciminero
University of Georgia

A self-report heterosocial skills inventory for females (SHI-F) was developed and was found to have satisfactory test-retest reliability, excellent internal consistency, and significant correlations with self-reported assertiveness and anxiety measures. An initial validity study compared high and low SHI-F scorers in analogue situations in which self-report, behavioral, and heart rate measures were taken. Although heart rate did not differ between groups, some behavioral and all self-report differences were significant. Additional data suggest that the SHI-F is more a measure of social skills and general negative self-evaluations and less a measure of interpersonal anxiety.

Recently there has been a growing interest in including persons who have difficulties in heterosocial situations as subjects in analogue treatment studies. Since the difficulties are thought to be characteristic of "minimal daters," college students who report infrequent dating have often served as subjects. Studies on minimal daters have shown their problems to be frequently occurring (Martinson & Zerface, 1970), clinically relevant (Curran, 1975; Twentymen & McFall, 1975), and not ameliorated by demands or suggestions for improvement (Borkovec, Stone, O'Brien, & Kaloupek, 1974). However, most of the studies in this area have been primarily concerned with treatment techniques and have neglected subject selection and assessment procedures. In addition, most of these studies have focused exclusively on male undergraduates, thus neglecting the female population.

The present study developed and initially validated an instrument for females based on Twentymen and McFall's (1975) Survey of Heterosexual Interactions (SHI). The Survey of Heterosexual Interactions for Females (SHI-F) was made as similar as possible to the SHI. Each survey contains four questions on dating frequency and 20 heterosocial situations in which the subjects are requested to rate on a 5-point scale their ability to initiate or carry on a conversation in that situation. An item on requesting the subject to rate her physical at-

tractiveness was added to the SHI-F. A low score on the SHI-F indicates a less heterosocially skilled individual.

The first part of this study collected normative and reliability data and described the characteristics of subjects selected by the SHI-F. The SHI-F was administered to 256 undergraduate females in introductory psychology classes at the University of Georgia. The mean score on the SHI-F was 68.28, with scores ranging from 32 to 98. The standard deviation was 11.78. The internal consistency of the SHI-F was substantially high as measured by the coefficient alpha ($\alpha = .89$), and its test-retest reliability was acceptable, $r(38) = .62$, $p < .001$. High and low scorers (at least 1 standard deviation above or below the mean) on the SHI-F did not differ on questions requesting them to estimate their average number of dates. However, high scorers reported dating a significantly greater number of different males per year, $t(73) = 2.75$, $p < .01$, rated themselves as participating in a greater amount of heterosocial behavior, $t(72) = 3.35$, $p < .01$, and rated themselves as significantly more attractive, $t(71) = 3.62$, $p < .001$, than the low scorers. In addition, the SHI-F was significantly correlated with the Rathus Assertiveness Scale, $r(119) = .558$, $p < .001$, and the Trait portion of the State-Trait Anxiety Inventory, $r(117) = -.404$, $p < .001$.

From the initial 256 subjects, a group of 15 high scoring and a group of 15 low scoring subjects were compared in six heterosocial situations in which physiological, behavioral, and self-report measures were collected.

The heterosocial situations were adapted from Rehm and Marston (1968) and required each

Requests for reprints and for an extended report of this study should be sent to Carolyn L. Williams, Department of Psychology, University of Georgia, Athens, Georgia 30602.

subject to interact over an intercom with a male confederate who was in an adjacent room. An example of the situations is as follows: "You run into a guy you dated a few times in high school in a drugstore near campus. He says 'Hi, I didn't know you were going to school here.'"

Subjects were asked to respond to the male as if they were actually in the situations described. During each situation the subject's heart rate was monitored via biotelemetry equipment. No significant differences between the two groups were found on heart rate. This contrasts with Twentyman and McFall's (1975) study, in which some analyses of the heart rate data revealed significant differences between males scoring high and low on the SHI. For females, the physiological response channel did not differentiate between the two groups.

Several behavioral measures were also taken during the six social behavior situations. Two observers rated the subject's overall anxiety and social skill plus three specific anxiety indicators and three specific social skill indicators during each scene. They also rated the subject's physical attractiveness after the last situation. Two time measures, duration and latency of response, were also recorded for each scene. (Interrater reliabilities for the behavioral and physiological measures are presented in the extended report.)

Significant differences were found on observer-rated social skill, with the high group being rated as more socially skilled, $t(28) = 2.17$, $p < .05$. Two of the three specific social skill indicators, interest and initiation, also differentiated between the two groups, with subjects in the high group rated by observers as showing more interest, $t(28) = 2.29$, $p < .05$, and more initiation, $t(28) = 1.95$, $p < .05$. The groups were not rated as different on the overall anxiety measure, on any of the specific anxiety indicators, on physical attractiveness, or on either of the time measures.

The subjects also rated their own overall anxiety and social skill in each scene. In contrast to the behavioral measures, the two groups differed on both social skill, $t(28) = 4.36$, $p < .001$, and anxiety, $t(28) = 4.89$, $p < .001$, in the situations. The low group subjects also rated

themselves as less attractive than the high group subjects, $t(28) = 3.03$, $p < .01$. Thus, it appears that low scoring subjects on the SHI-F perceive themselves and their behavior as less adequate than do independent observers.

These results point to the necessity of a multiple channel approach when studying a new self-report device and assessing the differences between groups. If only the self-report channel had been used in the present study, it would have appeared that the SHI-F measured both heterosocial skill and anxiety. However, the additional information from the behavioral channel suggested that the SHI-F was a heterosocial skills inventory.

The results of this study demonstrated the SHI-F to be a reliable and potentially useful instrument for selection of female subjects for analogue research in the heterosocial skills area. Use of the SHI-F in this manner would ensure more precise specification of subjects and more standardization across studies with females. Further research is needed to examine additional psychometric properties of the SHI-F and its use as an outcome measure in treatment studies.

Interpersonal Liking and Self-Disclosure

Richard Gelman and Hugh McGinley
University of Wyoming

Sixty-six female subjects viewed a videorecording of a female stranger who discussed her opinions about 10 social issues. After this, the subjects rated the stranger on the Interpersonal Judgment Scale and indicated on the Jourard Self-Disclosure Questionnaire what topics they would be willing to discuss with the stranger. What the subjects would discuss was found to be positively related to their characteristic level of disclosure and their attraction toward the stranger. The implications of the results for therapist-client interactions are discussed.

Self-disclosure can be viewed as a process in which an individual purposely communicates information about himself or herself. It is a topic that in the last several years, has become the focus of considerable research activity. Partially, this activity can be related to the assumed importance of self-disclosure to mental health. Some therapists and counselors believe that it is vital to have knowledge of significant aspects of their clients' lives if they are to work effectively with them. Inasmuch, a clear understanding of the effect of their own self-disclosure on the clients' self-disclosure would be useful to them.

Perhaps the strongest finding in the clinical analogue study of self-disclosure is that individuals are willing to disclose more about themselves to others whom they like than to others whom they dislike or regard with indifference (Fitzgerald, 1963; Halvorsen & Shore, 1969; Jourard & Lasakow, 1958; Worthy, Gary, & Kahn, 1969). Based on the relationship between self-disclosure and liking, it seems reasonable to expect variables that affect interpersonal liking to also influence self-disclosure. A variable that has been unequivocally shown to influence interpersonal liking is attitude similarity.

The assumption is that attitude similarity is a positive reinforcement (Byrne, 1971) and that people are interpersonally attracted to others who are associated with the positive emotional states that are elicited by reward, the similar attitude (Lott & Lott, 1968). Knecht, Lippman, and Swap (1973) have used attitude similarity as a manipulation of interpersonal

liking in a self-disclosure study. In this study, subjects perused an attitude questionnaire that had been purportedly filled out by a stranger who was either similar or dissimilar to the subjects in attitude. After their perusal of the questionnaire, the subjects rated the stranger on the Interpersonal Judgment Scale (IJS) and then indicated what they would be willing to discuss with the stranger. Knecht et al. found that subjects were willing to discuss more items with a stranger who held similar attitudes as compared to dissimilar attitudes. However, based on trends in their data, Knecht et al. suggested that it was attraction (liking) toward the stranger that determined the subjects' willingness to disclose, and not attitude similarity *per se*.

The purpose of the present study was to further investigate the relationship between liking, attitude similarity, and disclosure to a stranger.

Method

The subjects were 66 females from introductory psychology classes who had, 6-8 weeks earlier, completed a 36-item attitude survey. The materials of the study were four videotapes of a female stranger expressing her views on 10 of the items from the 36-item questionnaire, a Sony Videocorder, a 21-inch television monitor, the 40-item Jourard Self Disclosure Questionnaire (JSDQ; Jourard & Resnick, 1970), and the IJS (Byrne, 1971).

The subjects met in coacting groups of 2-8 persons. They first completed the JSDQ by indicating which items they would be willing to discuss with a female stranger of their own age. Next they viewed one of the four videotapes of a stranger talking about her attitudes, and then

Requests for reprints should be sent to Hugh McGinley, Department of Psychology, University of Wyoming, Laramie, Wyoming 82071.

they rated the stranger on the IJS. Finally, the subjects indicated on the JSDQ what they would be willing to discuss about themselves with the stranger. The stranger expressed different viewpoints on each of the four videotapes. This was done to ensure a wide range of attitude similarity-dissimilarity between the stranger and the subjects. This procedure is a modification of Byrne's (1971) standard stranger technique.

The score compiled for the JSDQ was the sum of the items the subjects indicated that they would be willing to discuss. These scores could range from 0 to 40. The IJS score was the sum of two items, liking and desirability as a work partner. This score could range from 2 to 14, with the lower score being positive. The attitude similarity-dissimilarity score was based on the differences between the stranger's expressed attitudes about the 10 topics that she discussed and the subjects' responses to these same 10 items on the attitude questionnaire. Each item offered eight possible answers ranging from "absolutely in favor" to "absolutely opposed." The subject's response to a given item was scored as zero if it was within one scale unit of the stranger's response, and it received a difference score of one for each unit of discrepancy thereafter, regardless of direction. The theoretical range of the attitude similarity score was 0-60, with a low score indicating attitude similarity.

Results and Discussion

The purpose of the first analysis was to discern which of the three variables, Disclosure 1 (the subject's first completion of the JSDQ), attitude similarity, or interpersonal liking (the IJS score), would best predict the subject's level of disclosure to the stranger (Disclosure 2). The regression equation for these data was $\text{Disclosure 2} = 9.75 + .77 \text{ Disclosure 1} - .94 \text{ Liking} - .08 \text{ Attitude Similarity}$. The multiple correlation coefficient was .77, $F(3, 62) = 30.06$, $p < .001$. The next analysis described the individual relationships between Disclosure 2 and the three predictor variables.

The standard regression method of decomposition was used (Nie, Hull, Jenkins, Steinbrenner, & Bent, 1975). In this method, each predictor variable is treated as if it had been added to the regression equation in a separate step after the other two predictors had been included. The amount of Self-Disclosure 2 variance explained by Disclosure 1 was significant, $F(1, 62) = 82.86$, $p < .001$, as was that explained by interpersonal liking, $F(1, 62) = 6.73$,

$p < .025$, whereas attitude similarity was not a significant predictor ($F < 1$).

As expected, the best predictor of the subject's disclosure to the stranger was her score on the first administration of the JSDQ. Beyond this, disclosure to the stranger was best predicted by her rating of the stranger on the IJS. This suggests that although self-disclosure may be an enduring trait, it is influenced by interpersonal liking, which is determined, in this study at least, by a variable or variables other than attitude similarity. This result raises a question. According to Byrne (1971), interpersonal attraction is directly related to the degree of attitude similarity between two people. Indeed, in the present study, the correlation between these two variables was .73 ($df = 64$, $p < .001$).

In the decomposition of the multiple regression, the liking score was significantly related to the subject's disclosure to the stranger, but attitude similarity was not. This suggests that although attitude similarity was a contributor to the liking score, its contribution was not significantly related to the subject's disclosure to the stranger. There was at least one other systematic contributor to the IJS score.

It is possible that there was an implicit attitude similarity that influenced the subject's attraction toward the stranger. The stranger's behavior of disclosing her attitudes about such topics as premarital sex and God implied both that she was willing to disclose and that she had a positive attitude toward disclosure. In the same vein, it can be said that a subject with a higher disclosure score would also have a positive attitude toward disclosure. Thus, a high disclosing subject shared a common and positive attitude with the stranger, whereas a low disclosing subject did not. Following from this, we would expect a high discloser, regardless of attitude similarity on other topics, to be more attracted to the stranger than a low discloser would be.

To test this possibility, the 66 subjects were trichotomized on the basis of their initial JSDQ scores, and the IJS scores made by the two extreme groups were compared. The high disclosers were significantly more positive toward the stranger than were the low disclosers, $t(42) = 3.15$, $p < .01$. Thus, similarity in self-disclosure was an important factor in determining the subject's attraction toward the stranger, and it was, apparently, this source of interpersonal liking that influenced the subject's disclosure to the stranger.

The results indicate that people are more attracted to others whose self-disclosure is simi-

lar to their own level of disclosure and that this attraction has an effect on the other's disclosure. This finding implies that the congruity of disclosure level between therapist and client may not be as crucial for the client whose characteristic level of disclosure is high, since the client is likely to continue her or his personal disclosure in the presence of the therapist. However, if a client who has a characteristically low level of disclosure perceives her or his therapist to be overly disclosing, then there is the possibility that the client might develop negative feelings toward the therapist that could preclude or interfere with successful counseling.

Reported Stressful Events During Developmental Periods and Their Relation to Locus of Control Orientation in College Students

Stephen Nowicki, Jr.
Emory University

To ascertain whether high levels of stress at different periods of development may be related to an external locus of control, 30 externals (15 males and 15 females) and 30 internals (15 males and 15 females) completed the Life Events Scale. Analysis of the data indicated that for females, stress in the preschool and pubescent, and for males in the elementary and pubescent, years was related to externality. It is suggested that there may be different critical developmental periods for males and females during which high levels of stress may be related to an external locus of control.

Most authors studying antecedents of locus of control assumed that children develop a locus of control orientation by reacting to continuous parental or environmental stimuli (see MacDonald, 1971). However, Bryant and Trockel (1976) have emphasized the possibility that noncontinuous events may determine whether a child becomes internal or external in orientation. Using Adler's assumption that "individuals particularly try to make sense of their stressful or perceived unusual life experiences" (cited in Bryant & Trockel, 1976, p. 266), Bryant and Trockel hypothesized that certain discrete stressful early life experiences may predispose the individual to an external orientation. To test such a proposition, these investigators administered a life stress questionnaire (Coddington, 1972) to females that covered four time periods: preschool, elementary, junior high school, and high school. As predicted, they found that females who expressed an external locus of control on the Adult Nowicki-Strickland Locus of Control Scale reported more stressful experiences during their preschool years than did the internal females. However, they neither replicated their results for females nor generalized them to males. If their findings could be confirmed for females *and* males, they would suggest strongly that the significant antecedents of locus of control orientation may occur before a child begins school and as a result of specific events as well as continuous interactions.

Requests for reprints and for an extended report of this study should be sent to Stephen Nowicki, Jr., Department of Psychology, Emory University, Atlanta, Georgia 30322.

The subjects for the present study were the top and bottom 30% of a group of subjects ($N = 103$) whose median Nowicki-Strickland Locus of Control score of 9 was comparable to that of Bryant and Trockel (1976). These subjects (15 female internals, 15 male internals, 15 female externals, and 15 male externals) completed Coddington's (1972) Life Events Scale. In Coddington's scale, the birth of a sibling was arbitrarily chosen as a midpoint and given a score of 50. Other events receive more or less than this arbitrary midpoint value.

Analysis of the data via a 2 (male vs. female) $\times 2$ (internal vs. external) $\times 4$ (preschool, elementary, junior high school, and senior high school) analysis of variance with repeated measures on the last factor revealed a significant three-way interaction, $F(3, 168) = 3.04$, $p < .05$. Subsequent post hoc testing via Newman-Keuls procedures suggested that as predicted, external females did report more stress during their preschool years than did internal females. However, further analysis also revealed that external females reported more stress during their junior high school years than did internal females, and external males reported more stress than internal males during their elementary and junior high school years.

It appears from these results that females and males do *not* share similar histories of stressful experiences. For females, it seems that the preschool, and for males the elementary, years may be differentially significant for the development of an external orientation.

However, it appears that events occurring at the tumultuous time of pubescence may be important for how much control males *and* females perceive that they have over their life. More

work with children at each of the three levels could substantiate whether stress or the locus of control orientation comes first. Males and females seem to have different vulnerabilities to stress and to the ability of that stress to affect their locus of control orientation. Further work needs to delineate the source of those sex differences as a function of time periods.

An Index of Premorbid Intelligence

Robert S. Wilson, Gerald Rosenbaum, Gregory Brown,
Daniel Rourke, and Douglas Whitman
Wayne State University

James Grisell
Lafayette Clinic, Detroit, Michigan

The aim of this study was to develop a way of estimating Wechsler IQs from demographic measures. The three summary IQs of the 1955 WAIS standardization sample were regressed on age, sex, race, education, and occupation. The resulting R^2 s were .53, .42, and .54 for the Verbal IQ, Performance IQ, and Full Scale IQ, respectively. The three regression equations provide actuarial indices of IQ that can be used as estimates of premorbid ability in neuropsychological assessment and research.

In neuropsychological assessment and research, there are a number of situations in which knowledge of subjects' premorbid IQ is desirable. Test data from the period preceding disease onset are, however, rarely available. Thus, clinicians are forced to estimate.

These estimates have relied on one of two data bases: (a) present ability measures thought to be relatively insensitive to neurologic disease (e.g., vocabulary) or (b) demographic information known to be related to IQ (e.g., education).

Although present ability measures such as vocabulary are highly correlated with IQ, their insensitivity to central nervous system disease is questionable. When compared with age-matched controls, neurologic patients in fact show a significant decline on all Wechsler Adult Intelligence Scale (WAIS) subtests (Russell, 1972). Impairment indices based on this model of estimating premorbid IQ have been ineffective in identifying cases of deterioration (e.g., Wechsler, 1958; Yates, 1956).

There have been two attempts to estimate premorbid IQ from demographic measures (Fogel, 1964; Ladd, 1964). The aim of both studies was to differentiate neurologic patients from controls. Subjects were assigned to one of four

educational categories. Control group means on several WAIS variables were then used as premorbid IQ estimates for patients with equivalent educational backgrounds. Use of these estimates improved Ladd's classification accuracy by 4%. Fogel did not report on the utility of the estimates.

These results are not dramatic, but they do suggest that the demographic approach may have merit, particularly given the reliance in these studies on a single demographic variable, education. Since adult onset disease should have little effect on demographic status, the accuracy of such estimates should be limited only by the correlation between IQ and the demographics. We assumed that this correlation could be substantially increased by the addition of other demographics known to be related to IQ (e.g., race, occupation). Our aim was, therefore, to develop multiple regression equations, based on a large, representative sample, that would permit estimation of premorbid IQ from demographic status.

Subjects ($N = 1,700$) consisted of the 1955 WAIS standardization sample minus the Kansas City elderly subjects (Wechsler, 1955, 1958). The three WAIS summary IQs (Verbal, Performance, and Full Scale) were regressed in a stepwise fashion on five demographic variables (age, sex, race, education, and occupation). Age and education were treated as continuous variables, whereas sex, race, and the 13 U.S. census occupation categories used by Wechsler were dummy coded (Cohen, 1968).

To simplify the equations, the unstandardized regression coefficients for the 12 dummy occupation categories were averaged across the three regression runs to yield a composite raw score

This article is based on a dissertation submitted by the first author under the direction of the second author.

Requests for reprints should be sent to Robert S. Wilson, who is now at the Department of Psychology and Social Sciences, Rush Presbyterian-St. Luke's Medical Center, 1753 West Congress Parkway, Chicago, Illinois 60612.

weight for each occupation category. The three IQs were regressed a second time on the demographic variables using these composite weights as occupation scores.

Education and race were the most powerful predictors in each equation. The r^2 s between education and Verbal IQ, Performance IQ, and Full Scale IQ were .44, .31, and .43, respectively. The R^2 s between all five demographics and Verbal IQ, Performance IQ, and Full Scale IQ were .53, .42, and .54, respectively. Thus, the four additional variables increased the amount of explained IQ variance by about 10%. With the exception of the negligible relation between sex and performance IQ, addition of each demographic variable significantly ($p < .01$) increased R^2 .

The regression equations that can be used to estimate premorbid IQ are as follows:

Estimated Verbal IQ =

$$(.18) \text{ Age} - (.02) \text{ Sex} - (.899)$$

$$\text{Race} + (3.09) \text{ Education} +$$

$$(.97) \text{ Occupation} + 70.80.$$

Estimated Performance IQ =

$$(.14) \text{ Age} - (.66) \text{ Sex} - (12.91)$$

$$\text{Race} + (2.44) \text{ Education} + (.91)$$

$$\text{Occupation} + 81.55.$$

Estimated Full Scale IQ =

$$(.17) \text{ Age} - (1.53) \text{ Sex} -$$

$$(11.33) \text{ Race} + (2.97)$$

$$\text{Education} + (1.01) \text{ Occupation} + 74.05.$$

In these equations, male = 1, female = 2, white = 1, nonwhite = 2, and the scores for Wechsler's (1955, p. 7) 13 occupation categories are 5, 1, 7, 7, 6, 3, 3, 5, 0, 1, 4, 10, and 0, respectively. The standard errors of estimate for the three equations are 10.2, 11.4, and 10.2, respectively.

These equations are based on 1955 data. The present applicability of the equations is an empirical question. If the formulae do permit

meaningful estimates of premorbid IQ, their use should aid in the identification of persons who have deteriorated intellectually. In a subsequent article we will show that these formulas can increase the accuracy with which the WAIS classifies persons as deteriorated versus normal by more than 10%.

Given the increase in educational attainment over the past 20 years, from a mean of 10.1 in the WAIS sample to a median of 12.3 in 1975 (U.S. Bureau of the Census, 1976), these equations can be expected to overestimate premorbid IQ. A partial solution to this problem consists of adjusting (deflating) the education weights in the equations to their 1955 level by multiplying the weights by .82 (10.1/12.3).

Relationships Among Marital Assessment Procedures: A Correlational Study

Gayla Margolin

University of California, Santa Barbara

This study examined the relationships among three methods for assessing marital adjustment: self-reports of marital satisfaction, spouse reports of pleasing and displeasing behaviors, and trained observers' coding of positive and negative communication behaviors. Frequency of pleasing behaviors was the only measure that correlated with global marital satisfaction. Inverse relationships were found between positive and negative scores for two of the three methods investigated.

Recent investigations into the quality of marital relationships have resulted in multiple procedures to measure relationship functioning. These procedures span a variety of observers (e.g., self, spouse, and trained others), settings (e.g., home and laboratory), targets (e.g., communication, companionship, sex, and affection), and methods (e.g., global ratings, daily observations, multibehavioral coding systems) (Weiss & Margolin, 1977). The purpose of this study was to describe the relationships among several of the most commonly used assessment procedures.

A social-learning formulation of marital adjustment suggests that marital dysfunction is related to (a) a disproportionately high exchange of displeasing, as compared to pleasing, events between partners and (b) reliance on coercive, rather than constructive, methods to bring about change in problem areas. To examine these facets of relationship functioning, this study used assessment methodologies that measure couples' (a) daily exchanges of pleasing and displeasing behaviors, (b) positive and negative communication behaviors, and (c) global impressions of marital adjustment. Each assessment methodology contained a positive and a negative dimension. On the assumption that spouse behaviors are related to marital adjustment, high correlations were expected between each behavioral measure and self-reported marital satisfaction.

The 27 couples who participated in this study were self-referred for marital counseling. Their average length of marriage was 10.8 years; their

mean spouse score on the Locke-Wallace inventory was 71.8. Couples were in the pretreatment assessment phase of their therapy at the time of this study. As part of this assessment, couples (a) completed a packet of self-report inventories, (b) came into the laboratory to videotape two 10-minute negotiation discussions, and (c) kept daily records of the pleasing and displeasing behaviors received from the partner during a 1-week period.

Two self-report measures of relationship satisfaction contained in the initial assessment packets were the Locke-Wallace Marital Adjustment Inventory, a traditional measure of marital adjustment, and the Areas of Change Questionnaire, which assesses the changes that each spouse desires for self and spouse in 34 common problem areas (Birchler & Webb, 1977). Daily frequencies of pleasing and displeasing behaviors came from the Spouse Observation Checklist (SOC), a 400-item listing of relationship behaviors that spans 12 categories of dyadic functioning. Each evening, spouses read through the checklist and indicated which pleasing or displeasing events had occurred during the previous 24-hour period. A pair of trained observers used the Marital Interaction Coding System (MICS) to assess communication skillfulness from the videotaped negotiation sessions. The 29 MICS codes include verbal and nonverbal behaviors that have been a priori assigned to positive (e.g., approval, agree), negative (e.g., criticize, no response), or neutral (e.g., question) summary scores. All of these assessment procedures, with the exception of the Locke-Wallace, were developed at the University of Oregon and Oregon Research Institute and are described elsewhere (c.f., Weiss & Margolin, 1977).

Requests for reprints should be sent to Gayla Margolin, who is now at the Department of Psychology, University of Southern California, Los Angeles, California 90007.

Table 1
Correlations Among Measurements for Assessing Positive and Negative Dimensions of Marital Relationships

Measure	1	2	3	4	5	6
Self-report data						
1. Locke-Wallace adjustment scores	(.90)**					
2. Areas of Conflict scores	-.43*	(.83)**				
Spouse observer SOC data						
3. Pleasing behaviors	.40*	-.04	(.94)**			
4. Displeasing behaviors	-.23	.25	.13	(.78)**		
Trained observer MICS*						
5. Positive communication behaviors	.02	.31	.21	.04	(.70)**	
6. Negative communication behaviors	.01	-.11	-.13	-.06	-.77**	(.83)**

Note. Within-method correlations are in boldface; split-half reliability values corrected by the Spearman-Brown formula are in parentheses; and the remaining values are across-method correlations. Mean frequencies for odd and even days were correlated for Spouse Observation Checklist (SOC) reliability values. Mean frequencies for two 10-minute segments were correlated for Marital Interaction Coding System (MICS) reliability values. $n = 27$; scores are based on husband-wife averages.

* Interobserver agreement = 83.8%.

* $p \leq .05$, two-tailed.

** $p \leq .001$, two-tailed.

The correlational matrix in Table 1 contains split-half reliability coefficients, within-method correlations, and across-method correlations. Split-half reliability coefficients were consistently significant. Within-method correlations revealed significant correlations for two of the three methods investigated: Adjustment scores were inversely related to conflict scores, and positive communication behaviors were inversely related to negative communication behaviors. However, the only significant correlation across methods was between marital adjustment and mean daily frequency of pleasing behaviors.

The results of this study illustrate the relative independence among several commonly used procedures to assess marital relationships. The hypothesis that each of the two behavioral measurements would correlate with a more traditional measure of global marital satisfaction was confirmed for SOC pleasing behaviors but not for communication behaviors. Although previous studies have shown that communication skills discriminate between distressed and nondistressed couples, data from this study on distressed couples do not indicate a relationship between observers' coding of communication skills and couples' subjective satisfaction ratings. Poor communication may be the earmark of marital distress, but it appears from these data that the intensity of the communication deficit does not correspond systematically with the level of overall distress.

The lack of correspondence between SOC pleasing and displeasing behaviors lends support to the repeated finding that these two dimensions vary independently. However, the low correlation between behavioral frequencies on the SOC and on the MICS was contrary to an earlier finding by Patterson, Hops, and Weiss (1975) on a sample of 10 distressed couples. Patterson et al.'s rank-order correlations between positive behaviors in the laboratory setting and daily reports of reinforcing exchanges at home were .85 for wives and .61 for husbands.

The overall lack of correspondence among measures used in this study is not an indication of invalid measurement procedures but rather is an indication that marital adjustment is not a unitary dimension. If marital adjustment does imply a set of independent dimensions, a thorough assessment must take account of these different dimensions and provide a profile analysis of each couple's strengths and weaknesses. From the results of this study, it appears necessary to use different data collection procedures to assess the various aspects of marital functioning. In light of these findings and the limited information about the psychometric properties of particular instruments, further investigation is needed to choose wisely from the wide range of available marital assessment options.

Effects of Uncertainty About the Behavior of a Phobic Stimulus on Subjects' Fear Reactions

John Lick

State University of New York at Buffalo

Mark Condiotte

University of Oregon

Thomas Unger

State University of New York at Buffalo

Two groups of rat-phobic subjects were repeatedly exposed to a live rat on a nearby platform under instructional conditions designed to induce different expectancies about the probability of the rat remaining on the platform. Although the rat's behavior was the same in both conditions, subjects who were led to believe that the rat might leave the platform evidenced significantly greater cognitive and physiological arousal to repeated rat exposures than did subjects who were informed that the rat would definitely not leave the platform.

An important methodological issue in laboratory research dealing with "small animal phobia" concerns stimulus differences between the laboratory and natural environment that may affect subjects' uncertainty about how a phobic stimulus will behave. For example, in the laboratory, subjects are usually exposed to caged animals in a context designed to foster the expectation that events are "under control" and nothing unpredictable will happen. In contrast, outside the laboratory, subjects are likely to encounter uncaged animals moving in an unpredictable fashion. The study reported here is designed to investigate the reactions of phobic subjects toward a fear-eliciting animal as a function of instructions designed to affect uncertainty about the behavior of that animal.

Subjects were 19 females from introductory psychology classes who received research credit for their participation. They were selected from a pool of 600 females who completed a questionnaire designed to assess fear of rodents.

When subjects arrived at the laboratory, they were told that the experiment involved investigating their physiological reactions to various stimuli. Subjects were then connected to a polygraph.

After a baseline period of 10 min, the experimenter entered the subject's room and told her that she would be exposed to two different stimuli.

The first would be a roll of masking tape, and the second a live, harmless rat. Subjects were informed that the experimenter would place each stimulus on the platform, leave the room for 25 sec, and then return to remove the stimulus. At this point subjects were given an opportunity to withdraw from the experiment, and, if they decided to continue, they were asked to sign a consent form. Three minutes after signing this form, the experimenter exposed subjects to the masking tape and the live rat, with an interstimulus interval of 2 min between presentations. (The interstimulus interval for all subsequent rat exposures was 25 sec, and subjects were asked to rate their cognitive anxiety on a scale from 1 to 10 between trials.) Subjects who showed greater physiological reactivity to the rat than to the masking tape were retained in the study and were randomly assigned to one of two experimental conditions.

In the certainty condition ($n = 10$), subjects were told that the rat they would be repeatedly exposed to for the rest of the experiment had stayed on the platform for hundreds of hours and could not leave it. To enhance the credibility of this message, subjects were shown an electric grid on the platform and were told that this grid had been used to successfully train the animal to stay there.

In the uncertainty condition ($n = 9$), subjects were informed that the rat would "probably" not leave the platform; however, in the highly unlikely event that this did happen, subjects were told that the experimenter would intervene immediately to capture the animal.

During each of the last 10 rat exposures, the

Requests for reprints and for an extended report of this study should be sent to John Lick, Department of Psychology, State University of New York at Buffalo, 4230 Ridge Lea Road, Buffalo, New York 14226.

experimenter rated the rat's activity level on a 5-point scale through a small window. After the last exposure, subjects were disconnected from the polygraph and were given a behavioral avoidance test. Following this, subjects completed the rodent questionnaire again and an additional question designed to assess how confident they were during the experiment that the rat would remain on the platform.

Preliminary analyses indicated that (a) there were no significant between-groups differences on any measures before the introduction of the instructional manipulation defining the independent variable, (b) the instructional manipulation was highly effective in inducing appropriate cognitive expectancies vis à vis the rat's probable behavior, and (c) the animal's activity level was not confounded with either trial or experimental conditions.

Subjects' cognitive and physiological responses to the rat following the induction of differential expectancies were analyzed by repeated measures analyses of variance. The results of this analysis for the cognitive data indicated significant main effects for condition, $F(1, 17) = 21.1$, $p < .001$; trials, $F(9, 153) = 14.3$, $p < .001$; and the Condition \times Trials interaction, $F(9, 153) = 3.61$, $p < .001$. The results for the electrodermal response data show significant main effects for condition, $F(1, 17) = 17.1$, $p < .001$, and trials, $F(9, 153) = 7.43$, $p < .001$, but no significant Trials \times Condition interaction, $F(9, 153) = 1.19$, $p > .30$. Similarly, the heart rate data showed significant main effects for condition, $F(1, 17) = 7.85$, $p < .02$, and trials, $F(9, 153) = 6.82$, $p < .001$, and no significant Trials \times Condition interaction, $F(9, 153) = 1.02$, $p > .50$. Overall, these results show that subjects in the uncertainty condition manifested significantly more cognitive and physiological fear during the 10 rat exposures than subjects in the certainty condition. In addition, subjects in the certainty condition showed a significantly faster rate of cognitive fear habituation than uncertainty condition subjects.

Finally, results from the behavioral avoidance test indicated that subjects in the uncertainty condition completed an average of 9.9 steps (higher numbers indicating more approach), whereas certainty subjects completed a mean of 5.9 steps, $t(17) = 3.55$, $p < .002$. In contrast, pre-post differences on the rodent questionnaire failed to discriminate between the two experimental conditions, $t(17) = 1.45$, $p > .15$.

The results of this study appear to have several implications for laboratory research with subjects who are afraid of small animals. First, the results call into question the external valid-

ity of the laboratory-based behavioral avoidance test. Since this test assesses subjects' fear reactions to a caged phobic stimulus in an experimental context associated with safety and predictability, it is possible that subjects might show fear reductions on this measure without manifesting concomitant fear reductions to uncaged animals moving in unpredictable ways outside the laboratory. Although this issue requires additional study, the available information suggests that this lack of generalization may not be uncommon (e.g., Lick & Unger, 1975).

This study also has implications for research investigating habituation phenomena (e.g., Watson, Gaiend, & Marks, 1972) and paradoxical fear enhancement (e.g., Stone & Borkovec, 1975). Specifically, the significant Trials \times Condition interaction for the cognitive fear measure suggests that the slope of the curve describing subjects' habituation to repeated presentations of a phobic stimulus can be influenced by situational variables affecting the threat value of that stimulus. In this respect, cues that affect subjects' cognitive appraisal of the probability of a phobic stimulus suddenly approaching them may be particularly important in determining level of threat. This is important, since studies investigating habituation and fear-enhancement phenomena have used phobic stimuli consisting of either caged animals or slides, and subjects may habituate to these stimuli substantially faster than they would to stimuli that are much more threatening (e.g., encountering a moving animal in close proximity).

Finally, the significant effect of the instructional manipulation on subjects' behavioral avoidance test performance justifies additional attention because it suggests that the effectiveness of fear-reduction techniques using in vivo exposure might be enhanced by structuring some of these exposures under conditions more closely approximating those characterizing naturalistic encounters with phobic stimuli.

Some Useful Statistics for the Interpretation of the WISC-R

Terry B. Gutkin
University of Nebraska—Lincoln

A verbal comprehension deviation quotient (VCDQ) and a perceptual organization deviation quotient (PODQ) are presented as alternatives to the Verbal and Performance IQs when attempting to measure the Wechsler Intelligence Scale for Children-Revised Verbal Comprehension and Perceptual Organization factors. The superiority of the VCDQ and PODQ rests on their equally high reliabilities, equal ease of computation, and improved factorial validity when compared with the Verbal and Performance IQs. To aid in scatter analysis research, techniques that permit a determination of whether individual subtests deviate significantly from the subtest mean of the VCDQ and PODQ are discussed. Formulas are also presented for the computation of a freedom from distractibility deviation quotient (FDDQ) to measure the Freedom from Distractibility factor. Unlike the VCDQ and PODQ, an inconsistent pattern of factor loading mandates the use of age-specific formulae for the FDDQ. Reliability data indicate that the FDDQ should be used primarily for research purposes and only with considerable caution in applied settings.

Kaufman's (1975) factor-analytic investigation of the Wechsler Intelligence Scale for Children-Revised (WISC-R; Wechsler, 1974) standardization data has provided psychologists with a well-grounded empirical framework within which WISC-R scores can be analyzed with a maximum of objectivity. Among the study's major findings were the discovery of Verbal Comprehension, Perceptual Organization, and Freedom from Distractibility factors, all of which appeared across the entire age range of the normative sample. Kaufman advocates that the Verbal IQ be taken as a rough equivalent for the Verbal Comprehension factor. Unfortunately, the inclusion of the Arithmetic subtest score in the computation of the Verbal IQ, in conjunction with the failure of the Arithmetic subtest to show any substantive loadings on the Verbal Comprehension factor, results in the Verbal IQ being an impure measure of the Verbal Comprehension factor.

A better measure of this factor would be a linear combination of only the Information (I), Similarities (S), Vocabulary (V), and Comprehension (C) scores, as all of these subtests show substantial loadings on the Verbal Comprehension factor. Working from procedures outlined by Guilford (1954), it was determined

that such a linear combination would be as reliable as Wechsler's (1974) Verbal IQ. In fact, the reliabilities for the proposed linear combination and the Verbal IQ never differ by more than .02 of a point at any age level between 6½ and 16½. A simple formula for the conversion of this factor score into a verbal comprehension deviation quotient (VCDQ), with a mean of 100 and a standard deviation of 15, was developed with the aid of procedures discussed by Tellegen and Briggs (1967). $VCDQ = 1.47 (I + S + V + C) + 41.2$.

In a similar vein, it is suggested that the Performance IQ is not the best measure of a subject's perceptual organization skills. The Coding subtest, which is included in the computation of the Performance IQ, shows only trivial loadings on the Perceptual Organization factor at every age level. Using the Tellegen and Briggs (1967) procedures, the following formula was derived for computing a perceptual organization deviation quotient (PODQ) with a mean of 100 and a standard deviation of 15. $PODQ = 1.60 (PC + PA + BD + OA) + 36.0$. (PC = Picture Completion; PA = Picture Arrangement; BD = Block Design; OA = Object Assembly.) Reliability coefficients for the PODQ were computed for ages 6½-16½ and were never more than .01 of a point discrepant with those found by Wechsler (1974) for the Performance IQ.

With equivalent reliability, equal ease of computation, and superior factorial validity the VCDQ and PODQ should prove to be more

appropriate measures of verbal and nonverbal intellectual skills than the more traditional Verbal IQ and Performance IQ scores. The impact of using the VCDQ and PODQ versus the Verbal IQ and Performance IQ was examined using the WISC-R scores of all children who were referred for psychological examinations in a south-west urban school district over the period of a full school year ($N = 275$, average Full Scale IQ = 76, $SD = 13$). The results showed that despite very high correlations between the VCDQ and Verbal IQ ($r = .98$) and between the PODQ and Performance IQ ($r = .96$), important score shifts were quite common. Wechsler (1974) stated that verbal-performance discrepancies of 15 points or larger are "important" and call for further investigation. When comparing the magnitude of verbal-performance discrepancies using the VCDQ-PODQ scores instead of the Verbal IQ-Performance IQ scores, 8% of the students changed from either an important to an unimportant discrepancy or vice versa. An additional 16% of the group changed from either a nonsignificant to a significant discrepancy (a difference of 12 points or more) or vice versa. A further indication that the use of the VCDQ and PODQ scores in lieu of the Verbal IQ and Performance IQ scores may substantially affect test interpretation comes from the finding that 20% of the referred students had a score differential between either the VCDQ and Verbal IQ or the PODQ and Performance IQ of 7 points or more.

Since many of the WISC-R subtests have adequate subtest specificity (Kaufman, 1975), the investigation of subtest scatter may be of interest to researchers. One common technique of scatter analysis has been to determine if any particular subtest score is significantly different from the average of other subtest scores that purport to measure similar abilities (Davis, 1959).

Tables 1 and 2 provide the difference scores needed to determine if any of the individual

Table 1

Table 2

*Minimum Deviations from the PODQ
Subtest Average Required for Statistical
Significance*

p	PC	PA	BD	OA
.05	2.48	2.62	2.18	2.77
.01	3.27	3.45	2.87	3.65

Note. PODQ = perceptual organization deviation quotient; PC = Picture Completion; PA = Picture Arrangement; BD = Block Design; OA = Object Assembly.

subtest scores that comprise the VCDQ and PODQ are significantly different from the average of all the subtest scores that comprise the VCDQ and PODQ. For example, if a subject's scores on the PODQ subtests are PC = 8, PA = 14, BD = 9, and OA = 9, the average for these subtests is equal to 10. The deviation from the PODQ average for each subtest is as follows: PC = -2, PA = 4, BD = -1, OA = -1. Table 2 shows that only the PA score differs significantly from the mean of the PODQ subtests ($p < .01$). The specific interpretation of any difference obtained in this manner will hinge on whether or not the subtest in question has adequate subtest-specific variance at the age level of the subject taking the test and on an analysis of what a particular subtest purportedly measures.

Although Sattler (1974) has presented a formula for the calculation of a freedom from distractibility deviation quotient (FDDQ), it is of questionable validity for several of the age levels that are encompassed by the WISC-R. Specifically, the Sattler formula is based on a linear composite score for the Arithmetic (A), Digit Span (DS), and Coding (Co) subtests. Even though these subtests do show substantial factor loadings on the Freedom from Distractibility factor at most age levels, the Co subtest has trivial loadings at the 6½-, 7½-, 14½-, and 16½-year levels (Kaufman, 1975). Sattler's formula, $FDDQ = 2.2 (A + DS + Co) + 34.0$, is thus appropriate for all age levels other than 6½, 7½, 14½, and 16½. The Tellegen and Briggs (1967) technique was used to compute an alternate formula for use at these four specific age levels: $FDDQ = 2.94 (A + DS) + 41.2$. It is important to note that for all age groups, the reliability of the FDDQ falls below .90 (ranging from a low of .83 at the 14½-year level to a high of .88 at the 12½-year level). Generally, .90 is accepted as the minimum reliability co-

efficient for scores that are used to discriminate among individuals (Nunnally, 1967). The FDDQ should thus be used primarily for research purposes and only with considerable caution in applied settings. The user must also keep in mind that unlike the VCDQ and the PODQ, the FDDQ measures a behavioral rather than a cognitive domain.

Symptom Contamination of the Schedule of Recent Events

Robert E. Lehman
University of Idaho

Three hundred fifty-seven subjects completed the Schedule of Recent Events (SRE) and a widely used symptom scale. The correlation between unit weighted SRE scores and the symptom measure was significant and did not improve when the SRE scores were weighted by life change units. Four items from the SRE were identified as possibly representing symptoms in and of themselves. Correlations between each SRE item and the symptom measure were calculated, and it was found that these four items correlated more highly with the symptom scores than all but two of the remaining items from the SRE. It is suggested that because certain SRE items apparently represent symptoms, observed correlations between the SRE and various symptom measures may be artifactually high.

A growing body of research has demonstrated that an accumulation of life events may impair psychological functioning and may contribute to the development of psychopathology (Dohrenwend, 1973; Myers, Lindenthal, Pepper, & Ostrander, 1972; Paykel et al., 1969; Vinokur & Selzer, 1973). The Schedule of Recent Events (SRE), developed by Holmes and Rahe (1967), has been widely used to assess the accumulation of life events in such studies. The scale comprises 43 items that represent changes in personal behavior and life circumstances. Each item is assigned a weight termed the *life change unit* (LCU), based on the average of judges' estimates of the adjustive demand required by each event. These range from a low of 11 to a high of 100. The total score is the sum of the weights of those items checked as having occurred within the last 12 months. Numerous studies have demonstrated significant correlations between SRE scores and the development of both psychological and physical dysfunctions. (See review by Rahe, 1972.)

However, Rahe (1974) has noted that the LCU weightings, as compared to unit weightings, are not important in subject populations that report low to moderate magnitude events. One purpose of the present study was to further test this observation.

In addition, examination of the individual items on the SRE suggests that some of the

items may, themselves, represent symptoms of disturbed functioning. For purposes of the present study, four items were identified as generally symptomatic of a wide range of disorders. These are "change in eating habits," "change in sleeping habits," "change in social activities," and "revision of personal habits." To the extent that these items on the SRE also represent symptoms, correlations between SRE scores and symptom measures will be artifactually high. A second purpose of the present study was to further explore this possibility.

Three hundred fifty-seven undergraduate students at the University of Idaho were administered the SRE and a widely used symptom scale (Langner, 1962) that has been found to correlate with the SRE. The mean LCU of items checked by these subjects was 23.94 ($SD = 4.57$), which is quite close to the mean of approximately 25 LCUs for Rahe's (1974) navy subjects. Scores on Langner's symptom scale had a mean of 4.29 ($SD = 3.00$). Subjects were blind to the purpose of the experiment, and the order of administration of the scales was counter-balanced.

As anticipated for this low-LCU sample, the use of LCU weightings did not improve the correlations between the SRE and symptom scale. The product-moment correlations for weighted and unweighted scores were almost exactly the same ($r = .23$, and $r = .22$, respectively). Both were statistically significant ($p < .001$, two-tailed). These results further confirm previously observed relationships between SRE scores and disturbed functioning. They also support Rahe's (1974) contention that "when using the LCU magnitude scale with a sample of

Requests for reprints and for an extended report of this study should be sent to Robert E. Lehman, Department of Psychology, University of Idaho, Moscow, Idaho 83843.

subjects who report primarily low to moderate LCU events . . . one can dispense with the LCU scale" (p. 82).

A likely explanation for this phenomenon is that the LCU weights of the items most frequently affirmed by low-LCU-magnitude subjects do not differ a great deal. For example, the lower half of the scale (i.e., that half of the scale with the lowest LCU magnitude weights) represents less than one third of the range of the entire scale. Thus, because the LCU weights of these items are relatively similar, use of the weights may provide little advantage.

To assess the possibility that certain items on the SRE represent symptoms and may thus inflate correlations between SRE scores and measures of maladjustment, the correlations between each item from the SRE and the symptom scale were calculated. The resulting point-biserial correlations ranged from $-.063$ to $.202$. The four items mentioned above as probable symptoms were isolated and were found to have correlations ranging from $.133$ to $.202$, with a mean of $.167$. All were significant at the $.02$ (two-tailed) level. The mean correlation of the remaining items, in contrast, was only $.048$. Furthermore, the four "symptom" item correlations were larger than all but two of the remaining items. This was in spite of the fact that the symptom items had a considerably lower mean LCU score ($M = 18.25$) than the remaining items ($M = 36.34$). The fact that these four symptom items generally exhibit much higher correlations with the symptom scale than do the other items suggests that they strongly contribute to observed relationships between SRE scores and symptom measures.

To the extent that the SRE contains items that are symptomatic of disturbed functioning, correlations between the SRE and measures of symptomatology will be artifactually high. Indeed, Hudgens (1974) has noted that as many

as 29 of the 43 SRE items could represent symptoms or consequences of illness. It is not suggested that the observed detrimental effects of stressful life events on physical and psychological health are entirely artificial by-products of the existence of symptom items on the SRE. However, it is probable that they do contaminate the SRE. This possibility warrants attention in future research.

The Polydrug Assessment Scale: A Psychometric Technique for the Indirect Measurement of Drug Use

Khalil A. Khavari and Frazier M. Douglass IV

Midwest Institute on Drug Use, University of Wisconsin—Milwaukee

Presently, there are no psychometric instruments for the indirect measurement of polydrug use. To ameliorate this situation, self-report data from 335 college students were examined to identify a set of personality-attitudinal items that correlated best with polydrug use. Twenty items emerged as reasonably stable correlates of drug use. Additional analysis showed that the 20 items, when treated as a scale, were reliable, diagnostically accurate, and applicable to either sex. Thus, this work represents an initial step in the development of a scale for indirect measurement of an individual's extent of involvement with use of psychotropics.

Psychometric instruments are valuable tools in the area of substance abuse. Several instruments and procedures have been developed to assess alcoholism (Jacobson, 1976) and narcotic addiction (Siegel, 1976). However, no indirect instrument has been available for measurement of polydrug use. Thus, the purpose of the present study was to develop a psychometric instrument to measure indirectly the extent of each person's involvement with a variety of psychoactive substances.

Data for this purpose were obtained from 335 college undergraduates, who voluntarily completed a brief questionnaire and returned it anonymously. The questionnaire contained 132 statements (similar to Minnesota Multiphasic Personality Inventory items) presented with a Likert response format and 19 questions about current usage of various licit and illicit drugs. Responses from the drug use questionnaire were transformed to *T* scores and were averaged to yield a criterion measure of polydrug usage. (See Douglass & Khavari, in press.)

To select items for the Polydrug Assessment Scale (PAS), responses to the 132 items were

first correlated with the criterion. Then, all items with correlations less than .20 were excluded from further consideration. The remaining 50 items were then subjected to a series of multiple regression and cross-validation analyses until an accurate and stable set of 20 items was identified. Finally, these items were further examined to determine their reliability and their applicability to selected subgroups of respondents.

The resulting set of items are listed in Table 1. Their relationship with the criterion is reflected by bivariate correlations (absolute value) ranging from .21 to .51. When combined and regressed on the criterion in a random sample ($N = 166$), these items accounted for 61% of the variance associated with polydrug usage ($R = .78$, $p < .001$). Resulting regression coefficients were then used to cross-validate items using the remaining respondents. The sum of these weighted items (PAS score) accounted for 47% of the polydrug variance ($r = .69$, $p < .001$). Since results from these two analyses were comparable, all subjects were pooled for summary computations. The mean and standard deviation for the pooled group were 49.64 and 4.29, respectively. Multiple regression coefficients are presented in Table 1.

This study was supported by Research Grant DA01080 from the National Institute on Drug Abuse and funds from the College of Letters and Science and the Graduate School of the University of Wisconsin—Milwaukee to K. A. Khavari. We thank Phil Farber for his invaluable contributions to this work.

Requests for reprints and for an extended report of this study should be sent to K. A. Khavari, Department of Psychology, University of Wisconsin—Milwaukee, Milwaukee, Wisconsin 53201.

Discriminative efficiency of the PAS was assessed by first dividing respondents into above average and below average polydrug users and then determining the correspondence between PAS scores and actual usage. A PAS score of 52, used as a dividing point, resulted in 81.5% correct classification; 24.18% were correctly identified as above average polydrug users,

57.31% were correctly identified as below average users, 6.57% were false positives, and 11.94% were false negatives. An increase or decrease in the PAS cutting point resulted in different percentages of correct and error classifications.

To examine the clinical utility of the PAS, respondents were divided into three groups (greater than +1 *SD*, between +1 and -1 *SD*, and less than -1 *SD*). Univariate analyses of variance showed that these three groups were significantly different in terms of all drugs except anti-infectious agents. People in the highest PAS group used every type of drug (except anti-infectious) more frequently than people with average PAS scores, and people with average scores used drugs more frequently than people with low PAS scores.

Examination of sex differences showed that males and females were not significantly different in terms of overall polydrug criterion scores or in terms of PAS scores. Thus, although males were more likely to use alcohol, marijuana, hashish, opiates, and cocaine, and females were more likely to use anti-infectious drugs, diet pills, tobacco, tranquilizers, sedatives, and relaxants, these differences are adequately controlled so that the PAS is applicable with either sex.

Since five of the PAS items specifically refer to drugs, some critics might contend that these items should not be included in the scale. Therefore, the multiple regression-cross-validation analyses were repeated after omitting the five items. The resulting correlation coefficients (.75 and .63, respectively) were not substantially different from values resulting from the full scale.

Reliability of the PAS was determined by applying the Spearman-Brown prophecy formula and by conducting a test-retest study with an additional group ($n = 17$). The Spearman-Brown reliability that was determined in the original group was .80, and the test-retest correlations were above .84 for most items (see Table 1).

These results show that the 20 items having low individual correlations with polydrug use can be combined to produce a stable instrument for indirectly assessing the degree of polydrug usage in males and females. Thus, the present scale is valuable for polydrug diagnostic purposes. It could be further developed by determining its use as a predictive device and identi-

Comparison of Symbolic and Overt Aversion in the Self-Control of Smoking

Oscar A. Barbarin
University of Maryland

This research compares rapid smoking (overt aversion), covert sensitization (symbolic aversion), and a combination of the two in a self-punishment procedure for reducing and eliminating cigarette smoking. Sixty adults (M age = 40) were randomly assigned to one of three experimental groups or to the control group. Ten training sessions were spaced over a 1-month period. The experimental groups smoked significantly less than the control group at each follow-up point. The overt group achieved significantly greater reduction than the symbolic group, and the combined group did not differ significantly from either of the single treatment groups. One year after treatment, 6 of 15 persons in the overt aversion group were completely abstinent, as opposed to 1 in each of the other experimental groups.

The present study examines the relative efficacy of symbolic and overt aversion in self-control procedures designed to eliminate smoking. Sixty adults (M age = 40) who smoked at least one pack of cigarettes a day were medically screened and assigned to one of three experimental groups (rapid smoking, symbolic aversion, combined treatment) or a control group. A week of self-monitoring prior to treatment provided the baseline against which treatment effects were to be measured. Training in each self-control strategy was conducted in 10 1-hour sessions spaced over a 1-month period. Treatment was carried out in groups of 3-7 persons. At each session participants were asked to report the number of cigarettes smoked since the previous session and whether they had used the self-control procedure to avoid normal smoking.

After 10 minutes of relaxation exercises, the overt aversion group began rapid smoking, which called for normal inhalations every 6 sec. Participants were paced by a prerecorded tone and a voice signal that simultaneously counted out consecutive numbers every 6 sec. Trial length and the latencies between trials were determined

by the participants. They were instructed to smoke as long as they could tolerate smoking. Group members recorded the number that they heard at the beginning and end of each trial, making it possible to calculate the number of inhalations per trial and the latencies between trials. At the end of each trial, participants also rated the aversiveness of their thoughts and physical reactions.

The symbolic aversion group was first asked to imagine as clearly as possible several scenes in which unpleasant consequences occurred as a result of smoking. Most scenes were drawn from situations listed by participants in their smoking logs compiled prior to treatment. Participants called to mind situations in familiar places such as homes, work, or with friends in which they frequently experienced the temptation to smoke. Then they were asked to imagine the occurrence of a variety of aversive consequences. In many instances these imagined consequences were isomorphic with the real consequences for the overt group, namely, nausea, coughing, dizziness, and discomfort in the chest. Other graphic images such as vomiting on self and uncontrollable coughing were also used to enhance the aversive nature of the imagined scenes. After the experimenter described an aversive scene, the participants imagined the scene. Following the aversive scenes, participants imagined an aversion relief scene that included the refusal to smoke. In these scenes participants imagined feeling calm, relaxed, and generally good about themselves. After each trial, members of the symbolic aversion group rated the vividness and

aversiveness of the scenes. Participants were asked to use the symbolic aversion procedure and the relaxation exercises when they felt an urge to smoke. In addition, they were asked to practice for 10 minutes twice a day.

The combined aversion group used both symbolic and overt aversion, as described above. Participants used relaxation exercises, imagined unpleasant consequences for smoking, and engaged in rapid smoking while concentrating on these unpleasant images. Members of the control group were told that they could not be accommodated in the training groups but that they would be sent descriptions of self-control procedures used in the program and that their

progress would be monitored through telephone contacts. Subsequently, they were sent publications of the American Cancer Society describing a self-directed plan for monitoring and gradual reduction of smoking. The control group was contacted weekly for 1 month and at each of the follow-up points. During the 4 weeks of treatment, they were asked about their progress and were encouraged to maintain their efforts to abstain from smoking. All participants were contacted 1 week, 2 weeks, 1 month, 2 months, 3 months, and 1 year following treatment.

One participant each from the symbolic and combined groups dropped out before follow-up could be completed. The resulting groups did not differ significantly with respect to sex, age, cigarette consumption, or previous attempts to quit smoking. A one-way analysis of variance was performed on the percentage of baseline smoking reported at each follow-up point. Table 1 presents the means, standard deviations, and F values for smoking rates from treatment to the 1-year follow-up. Significant differences were found at each point between the experimental groups and the control groups. In addition, overt aversion produced greater reductions in smoking than symbolic aversion. However, there were no significant differences between the combined group and either the symbolic or overt aversion

Table 2

Number of Abstinent Participants During Follow-Up

Group	Weeks after treatment					
	1	2	4	8	12	152
Symbolic ^a	4	4	3	3	1	1
Overt ^b	14	12	12	8	6	6
Combined ^a	7	6	6	5	3	1
Control ^b	1	1	1	1	1	0

^a $n = 14$.

^b $n = 15$.

groups. Interestingly, this pattern held up even at the 1-year follow-up.

A similar pattern was observed with respect to the number of participants maintaining abstinence (see Table 2).

The overt aversion group appeared decidedly superior to all other groups with respect to long-term maintenance of abstinence.

On a 9-point scale, the symbolic aversion group rated their images as significantly clearer than did the overt aversion group ($M = 7.72$ vs. 6.00). However, the symbolic group did not differ from the combined group ($M = 6.67$). In rating the aversiveness of physical reactions during aversion training, the symbolic aversion group ($M = 6.8$) was significantly lower than either the overt ($M = 8.2$) or the combined groups ($M = 8.2$). The combined groups had less training with the rapid-smoking technique than the overt group with respect to the number of trials (25.4 vs. 31.4), the number of cigarettes per session (5.1 vs. 7.1) and the total time in rapid-smoking training (167 vs. 200 minutes). At the end of treatment, participants rated the usefulness of various treatment components. The overt and combined groups rated rapid smoking as most useful, with group support second. The symbolic group gave highest ratings to relaxation training and group support.

The results of the study point to the superiority of overt aversion over symbolic aver-

sion in the self-control of cigarette consumption. This is true both with respect to the absolute level of smoking reduction and the number of individuals who were able to maintain abstinence. However, each of the experimental treatment groups smoked significantly less than the control group. These findings suggest that symbolic aversion shows promise as a self-modification procedure for gaining control over smoking behavior. The failure of the combined treatment group to achieve a level of smoking reduction superior to that of the symbolic treatment alone is perplexing. However, similar findings are reported by Danaher (1977), who combined several treatment components. It is likely that participants attempting to apply several techniques may not be able to master each of them fully. In this case, differences in the amount of training in the overt condition may also contribute to the diminished effect of the combined treatment group. Consequently, additional attention must be given to the effects of combining treatment.

Moderators of Racial Differences on the MMPI

Arthur I. Rosenblatt and David A. Pritchard
University of Mississippi

Multiple discriminant analysis of Minnesota Multiphasic Personality Inventory (MMPI) scores between high-IQ white, high-IQ black, low-IQ white, and low-IQ black subjects yielded two significant canonical variates. The results suggest that racial differences on the MMPI do not occur in all racial comparisons but instead are restricted to low-IQ groups.

In his review of racial differences on the Minnesota Multiphasic Personality Inventory (MMPI), Gynther (1972) concluded that

the degree of MMPI differences between blacks and whites appears to be affected by such variables as education, residence and cultural separation. (p. 390)

The largest racial differences reportedly occur among poorly educated, rural, and isolated subjects, whereas such differences are attenuated or even eliminated among better educated, urban, and integrated subjects. The empirical basis for this conclusion is unclear, however, since only one of the studies reviewed by Gynther (Erdberg, 1970) contained a factorial design to test the moderating effect of one of the hypothesized variables (i.e., residence: urban vs. rural). The remaining studies generally used fixed values for education (e.g., ninth graders), for residence (e.g., urban), and for cultural separation (e.g., segregated school), and thus provided no test of the moderating effect of these variables.

Since Gynther's (1972) review, only one study has specifically investigated the effect of one of Gynther's hypothesized moderator variables. Davis and Jones (1974) performed analyses of variance on each of the MMPI clinical scales using race, diagnosis (schizophrenic vs. "other disorders"), and education (12+ grades vs. 11 or fewer grades completed) as factors. They reported no significant main effects for race on the clinical scales, but they did find a significant Race \times Education interaction on the

Pa and *Sc* scales, with the less educated blacks scoring higher than the other groups.

In a related analysis of the same data, Cowan, Watkins, and Davis (1975) reported that only the poorly educated black nonschizophrenics were significantly misclassified as schizophrenic when an empirical rule was used to classify MMPI profiles into schizophrenic and nonschizophrenic groups. Both of these analyses support the hypothesis that racial differences on the MMPI are moderated by educational status. The present study attempts to replicate this finding on a new sample, using a more appropriate method of statistical analysis.

The subjects were 104 black and 191 white male inmates at the Mississippi State Penitentiary, who were each administered the Wechsler Adult Intelligence Scale (WAIS) and the MMPI as part of an evaluation for vocational rehabilitation services. Subjects ranged in age from 17 to 59 (white: $M = 25.8$, $SD = 7.54$; black: $M = 24.5$, $SD = 5.83$), and in education from 3 completed grades to 16 completed grades (white: $M = 10.7$, $SD = 2.32$; black: $M = 11.2$, $SD = 2.02$). All subjects scored above the standard score of 70 on the reading portion of the Wide Range Achievement Test (WRAT) (white: $M = 101.2$, $SD = 15.81$; black: $M = 91.1$, $SD = 13.0$). Over 90% of the subjects were new arrivals at the prison at the time of testing, whereas the remaining subjects had reached their time of parole eligibility.

Highest grade completed was rejected as a potential moderator variable, since a majority of the subjects had been in school prior to integration in Mississippi, and thus highest grade completed might not indicate an equal educational experience for the two racial groups. Instead, the Full Scale WAIS IQ was adopted as an approximate indicator of the kinds of differences that might moderate racial differences on the

This article is based on a master's thesis completed at the University of Mississippi by the first author.

Requests for reprints should be sent to David Pritchard, Department of Psychology, University of Mississippi, University, Mississippi 38677.

MMPI. The product-moment correlations between WAIS Full Scale IQ and WRAT scores were .64 (Reading, $p < .001$), .54 (Spelling, $p < .001$), and .70 (Arithmetic, $p < .001$), whereas the correlations between highest grade completed and WRAT scores were .32 (Reading, $p < .001$), .40 (Spelling, $p < .001$), and .35 (Arithmetic, $p < .001$). Thus, Full Scale IQ appeared to be a better indicator of educational achievement than highest grade completed.

The sample was divided into four subgroups defined jointly by race and by IQ score (dichotomized at the sample median of 93.0). The four groups were labeled high-IQ white ($M = 106.0$, $SD = 8.81$, $n = 121$), high-IQ black ($M = 100.8$, $SD = 6.68$, $n = 23$), low-IQ white ($M = 85.7$, $SD = 5.69$, $n = 70$), and low-IQ black ($M = 81.2$, $SD = 6.47$, $n = 81$). A multiple discriminant analysis (Klecka, 1975) was performed on these four groups using K -corrected raw scores on the MMPI's 10 clinical scales as variables. If IQ functions as a moderator of racial differences on the MMPI, then the resultant canonical variates should separate the low-IQ white and low-IQ black groups but not the high-IQ white and high-IQ black groups. On the other hand, if IQ does not moderate racial differences on the MMPI, then canonical variates should separate the racial groups within both the high and low IQ categories.

The first variate produced a Wilk's lambda of .6958, which is approximately equal to a chi-square of 104.1 ($df = 30$, $p < .001$; Overall & Klett, 1972). The second variate produced a Wilk's lambda of .8508 ($df = 18$, $p < .001$), and the third variate yielded a nonsignificant Wilk's lambda of .9766 ($p < .560$). The first variate accounted for 18.23% of the MMPI variance and separated the high and low IQ groups; the second variate accounted for 12.89% of the variance and separated the low-IQ white group from the low-IQ black group. Accordingly, the first variate can be interpreted as an IQ effect on MMPI scores, and the second can be interpreted as a (moderated) racial effect on MMPI scores. In support of this interpretation, it should be noted that the greatest contributions to the second (moderated racial) variate were made by Scales 1, 3, 8, and 9, as indicated by the relative magnitudes of the standardized discriminant weights for these scales. Blacks scored higher than whites on Variate 2 for Scales 1, 8 and 9, whereas whites scored higher than blacks on Scale 3. This is precisely the

pattern of racial differences on the MMPI that previous studies have reported most often (Gynther, 1972; Rosenblatt, 1976). It can thus be concluded that IQ moderated the effect of race on MMPI scores and that such racial differences were almost exclusively limited to lower IQ subjects.

Since the above results may have been influenced by the inclusion of "invalid" profiles (Costello, Tiffany, & Grier, 1972), the analysis was repeated five times on successive samples of the 295 profiles. The samples differed from each other only in the maximum F score allowable for inclusion, and thus represented successively more stringent criteria for profile validity. Results from these five analyses confirmed that the results obtained in the analysis of all profiles were not due to the inclusion of invalid profiles. In fact, the exclusion of profiles with high F scores increased the size of the IQ effect and the moderated racial effect on MMPI clinical scales.

Problems Associated With the Typological Measurement of Sex Roles and Androgyny

Jeffrey A. Kelly

Department of Psychiatry and Human Behavior
University of Mississippi Medical Center, Jackson

Wyndol Furman

University of Denver

Veronica Young

Belhaven College

Four new measures of sex role style (the Bem Sex-Role Inventory (BSRI) the Personal Attributes Questionnaire (PAQ) the Personality Research Form (PRF) ANDRO scale, and the Masculinity and Femininity scales of the Adjective Check List; ACL) each define sex role style and androgyny in similar conceptual and psychometric terms. Although these scales have often been used interchangeably, the current study is the first to examine interscale comparability among these inventories. Although correlations among the respective Masculinity and Femininity raw (continuous) scale scores on the BSRI, PAQ, PRF ANDRO scale, and the ACL were moderately high, a large proportion of subjects were classified into different sex role categories (masculine typed, feminine typed, androgynous, or undifferentiated), with the category depending on the inventory used. In fact, when corrected for chance agreements, the majority of subjects (61%) were actually categorized discrepantly by any pair of inventories. This suggests limited comparability of sex role research findings based on different inventories, and when sex role styles are dichotomized into broad typological quadrants, as is the current practice in sex role research, substantial predictive utility is lost.

Just as bipolar masculinity-femininity scales had once flourished, new sex role inventories based on a conceptual model using independent measurement of masculinity-femininity have proliferated recently. The Bem Sex-Role Inventory (BSRI; Bem, 1974), the Personal Attributes Questionnaire (PAQ; Spence, Helmreich, & Stapp, 1975), the PRF ANDRO scale (Berzins, Welling, & Wetter, 1978), and the Masculinity-Femininity scales of the Adjective Check List (ACL; Heilbrun, 1976) each define sex roles in similar terms, and each has been used to designate sex-typed androgynous, and undifferentiated roles. Because these four scales rely on highly similar definitions of sex roles, are all capable of designating androgyny, and all use similar scoring procedures to yield four sex role categories, the inventories have been

used almost interchangeably in recent sex role research.

However, Kelly and Worell (1977) have noted that while purporting to measure the same sex role constructs, each of these scales samples somewhat different content domains, were developed using different psychometric and item selection procedures, and were subjected to different criteria of validity and reliability. Further, although the four scales have been used interchangeably, no studies have directly compared these inventories. An important question is whether individuals categorized as sex typed, androgynous, or undifferentiated on one scale receive the same designation on another. If this were not the case, it would impose serious restrictions on the comparability of research findings based on different scales and would require further examination of configural sex role scoring procedures. The current study addresses the questions of interscale comparability and strategies of sex role categorization.

One hundred thirty (65 male and 65 female) undergraduate college students served as subjects in the study. All inventories were administered in fully counterbalanced order. Directions for completing each of the scales were those

used by each respective inventory's author. However, because time limitations precluded the administration of the entire ACL, only those ACL adjectives actually comprising the Masculinity-Femininity scales were administered. These adjectives were listed in random order on a checklist form.

The scales were then scored to yield separate Masculinity and Femininity scores for each student on the BSRI, PAQ, ANDRO scale, and ACL. Following the procedure advocated by each scale's author, subjects were considered masculine typed if they scored above the Masculinity scale median and below the Femininity scale median on an inventory. Those subjects whose Femininity scores were above the median and whose Masculinity scores were below the median were categorized as feminine typed. Persons were considered androgynous if they exceeded an inventory's masculinity and femininity medians, and they were considered undifferentiated if they fell below both medians on an inventory.

Pearson product-moment correlations were first calculated among the raw masculinity and femininity scores of all inventories. For sexes combined, interscale masculinity score correlations were BSRI/PAQ = .85; BSRI/ANDRO = .70; BSRI/ACL = .75; PAQ/ANDRO = .66; PAQ/ACL = .70; and ANDRO/ACL = .61. Interscale femininity score correlations were BSRI/PAQ = .73; BSRI/ANDRO = .62; BSRI/ACL = .68; PAQ/ANDRO = .59; PAQ/ACL = .51; and ANDRO/ACL = .57. The mean correlation between the four inventories' raw Masculinity scales was .71, and the mean correlation between Femininity scales was .62.

Since current approaches to sex role measurement assign subjects to one of four typologies, interscale comparability was further assessed by determining the percentage of subjects who were classified into the same sex category by each pair of scales. A crucial question is whether the same individuals are assigned to the same sex role categories across inventories. Table 1 reveals that the percentage of agreement in individual subject classification was quite low, averaging only 56% of the subjects between any two scales' categories (range = 52% agreement to 61% agreement for sexes combined and 49% to 63% for sexes separately). Thus, an average of 46% of all subjects were assigned to discrepant sex role categories when the classification outcomes of two inventories were compared.

To correct these results for interscale classification agreements due to chance, Kappa co-

Females	63.1	47.4

Note. BSRI = Bem Sex-Role Inventory; PAQ = Personal Attributes Questionnaire; ANDRO = Personality Research Form ANDRO scale; and ACL = Adjective Check List.

efficients (Cohen, 1960) were determined. When the percentage of agreement between the classification outcomes of inventories have been adjusted for chance, the mean Kappa percentage agreement drops to 39. Thus, the majority of subjects are actually classified discrepantly when a second sex role inventory is used. When the percentage of agreement in subject classification across all four sex role inventories was calculated, only 30% of the subjects were found to be categorized the same on all four inventories.

It is apparent that persons classified as androgynous, sex typed, or undifferentiated using one sex role scale may well be a very different subsample than persons with the same designation based on another scale. This is the case even when the scales purport to assess similar characteristics, use the same scoring procedures, and assign subjects with identical labels based

on their scores. These findings raise serious limitations concerning the comparability of research results when differing inventories are used.

In the current study, relatively high correlations were obtained between the Masculinity and, to a lesser degree, the Femininity scales of the four inventories when subjects' scores were treated as continuous variables. However, when subjects' scores were dichotomized by median split categorizations, many, and in some cases, most subjects are discrepantly classified. Lost variance and reduced predictive utility are exacerbated by the prevalent scoring procedure in which subjects are classified into four sex role categories on both the Masculinity and Femininity scales of a given inventory. Although masculinity and femininity as defined by these scales appear to be unrelated and should be measured separately, the current data indicate that there is little empirical basis for configurally combining these scores into broad, typological categories based on median splits. Multiple linear measurement or multiple regression analyses may enable future research to more precisely examine the adjustive and social-behavioral implications of sex role orientations.

Male and Female Treatment Differences: Can They Be Generalized?

Andrew C. Del Gaudio, Paul J. Carpenter, and Gary R. Morrow
Department of Psychiatry
University of Rochester Medical Center

The present study evaluated the generalizability of previous findings that male and female patients may receive differential psychiatric treatment. A comparison of 156 female and 66 male outpatients on demographic, clinical, and self-report measures of mood, symptoms, and interpersonal concerns revealed no sex differences. The treatment variables of length of therapy and the prescription of medication were the dependent measures. The results indicated that with a broad sample of male and female patients, there were no significant sex-related differences on the dependent variables. Thus, it is suggested that the generalization of sex-specific treatment differences be qualified.

A recent study by Stein, Del Gaudio, and Ansley (1976) found that a sample of neurotically depressed female outpatients had significantly more therapy sessions and were significantly more likely to be prescribed psychotropic medications, especially the more potent varieties, than were a sample of male neurotic depressives. These findings were obtained despite the fact that the male and female patients were indistinguishable on demographic, clinical, and self-report measures of symptoms, mood, and interpersonal concerns. Their data supported the findings of others (Abramowitz, Abramowitz, Roback, Corney, & McKee, 1976) that differential attitudes of clinicians, rather than patient factors, are a salient element in the psychotherapeutic process.

The present study examined the generalizability of the earlier study (Stein et al., 1976) by attempting to replicate the sex-specific findings with a different sample of patients representing a broader range of clinical diagnoses rather than a single category.

Subjects were 222 patients who were admitted to the same outpatient clinic used in the Stein et al. (1976) study. Demographic and clinical data were gathered on each patient, as well as their responses to the following measures of mood, symptoms, and interpersonal concerns: Terminator-Remainer Scale (TR), Hopkins

Symptom Rating Scale (HSRS, five subscales), Profile of Mood States (POMS, six subscales), FIRO-B (six subscales), and the Marlowe-Crowne Social Desirability Scale. The majority were white (84.6%), married (41.6%), middle class (68.3%), and female (70.3%).

A broad spectrum of psychiatric diagnoses was present in the sample: neurosis (37.9%); transient situational disorder (29.4%); personality disorder (15.8%); psychosis (7.7%); addictive states (2.3%); and deferred, unknown, and other diagnoses (6.9%); the other diagnoses chiefly included psychophysiologic disorders, organic brain syndrome, and mental retardation).

Chi-square comparisons of the male and female patients on the demographic variables of age, race, marital status, and education yielded no differences. Male-female differences in self-ratings of mood, symptoms, and interpersonal concerns examined by *t* tests revealed that (a) Female patients had significantly higher scores than males on the Depression subscale of the HSRS ($p < .05$); (b) males, on the other hand, had significantly higher depression scores than females on the POMS ($p = .05$); (c) males had significantly higher expressed control scores ($p < .01$) than did females on the FIRO-B.

Significantly elevated Depression scores for both male and female patients on different measures make it safe to assume that there are essentially no sex-specific differences on depression. The findings on the FIRO-B can be attributed to chance, since 1 significant result out of a possible 19 is within the statistical expectation of chance. Therefore, this study yielded no evidence that male and female psychiatric patients

Requests for reprints and for an extended report of this study should be sent to Paul J. Carpenter, who is now at the University of Southern Mississippi, P.O. Box 8482, Southern Station, Hattiesburg, Mississippi 39401.

entered treatment with significantly different levels or types of subjective distress and interpersonal needs and concerns, a result in agreement with the Stein et al. (1976) study.

The present investigation did not, however, reveal any sex differences in the average number of therapy sessions or the extent to which medications were prescribed. Thus, when the patient sample was expanded beyond a single diagnostic category (neurotic depression), no treatment differences emerged between male and female patients drawn from the same clinic population, as they did in Stein et al. (1976). This strongly suggests that limits be placed on the generaliza-

tion that differential psychiatric treatment is afforded to men and women.

Effect of Psychotomimetics (LSD and Dextroamphetamine) on the Use of Figurative Language During Psychoanalysis

Michael Natale
Department of Psychiatry
Columbia University

Michael Kowitt
Philadelphia Psychiatric Center
Philadelphia, Pennsylvania

Charles C. Dahlberg and Joseph Jaffe
Department of Communication Sciences
New York State Psychiatric Institute
New York, New York

This study examined the effect of LSD, dextroamphetamine, and a placebo on patients' use of figurative language in psychoanalytic sessions. A longitudinal design was performed on three male psychoanalytic patients who volunteered to receive each drug (LSD-50-100 u, dextroamphetamine-15 mg, placebo) seven times over a period of 1½ years. The patients, analyst, and raters were all blind concerning the drug condition. Forty-minute verbatim transcripts were scored for figurative language by two trained raters. Results showed that for two of the three patients, the use of nonliteral language, in particular, "novel" figurative phrases, was significantly increased by LSD.

The rationale for the clinical use of psychotomimetics (LSD, anticholinergics) is that they augment traditional psychotherapy by intensifying and accelerating transference, recall, loosening of defenses, and so forth (Abramson, 1967). Is there any empirical verification for these notions or do they remain presuppositions? Fink (1974) has presented evidence suggesting that psychotomimetics induce a decrease in syntactic "defensive language behaviors" (use of third-person reference and qualifiers, use of past tense instead of present tense). LSD-induced language changes are hypothesized to resemble the speech of acute schizophrenics. However, Gottshalk and Gleser (1969) presented contrary evidence to the effect that psychotomimetics do not promote "schizophrenic" speech, but they do promote

language that reflects a cognitive impairment (organicity).

In light of the above-cited contradictory findings, it is fair to state that the effects of LSD on the speech of normals is undetermined at present. The goal of this study was to clarify the effect of psychotomimetics on speech in (a) the examination of the *therapeutic* language effects of LSD, dextroamphetamine, and a placebo on patients' speech during actual psychotherapy sessions and (b) the use of a language measure that is significantly related to "insight" on the part of the patient. We (the experimenters) chose "figurative language" as a speech index of clinical change because investigators have become increasingly aware of the role of figurative language in psychotherapy; specifically, *novel* nonliteral language is associated with insight. (See Billow, 1977, for a review.) To sum up, the hypothesis of the present study can be stated as follows: Ingestion of LSD and dextroamphetamine is expected to cause an increased usage of novel figurative phrases by patients during psychoanalytic sessions.¹

Verbatim transcripts of three male psychoanalytic patients were used in the present study;

This research was aided in part by MH 13579, which supported the first author as a postdoctoral research fellow in the Interdisciplinary Research Training Program, Department of Psychiatry, Columbia University, and by MH 06470-19, which supported the second author as a psychology intern in the Department of Psychiatry, Columbia University.

The authors wish to express thanks to the William Alanson White Institute where the project was originally conducted.

Requests for reprints should be sent to Michael Natale, who is now at the Department of Psychology, University of Pennsylvania, 3813 Walnut Street, Philadelphia, Pennsylvania 19174.

¹ The interested reader is referred to Mechanek, Feldstein, Dahlberg, and Jaffe (1968) for a detailed description of the research project. What follows is a brief outline of the methodology.

the patients were white, college educated, and suffered from neurotic depression. All subjects provided informed consent to participate in the research project.

Each patient received each of the three drugs (LSD = 50–100 u; dextroamphetamine = 15 mg; placebo) seven times on a randomized schedule for a total of 21 experimental psychotherapy sessions over a period of 1½ years. Patients, therapist (CCD), and raters (MN and MK) were blind concerning the drug condition.

Each transcript was scored via Barlow, Kerlin, and Pollio's (1970) programmed scoring technique for the patients' use of figurative language by two raters. Fourteen categories of figurative language were scored, with each instance being classified as either "frozen" or novel. Frozen was defined as a figure of speech that is considered a part of common vocabulary. Novel was defined as a figure of speech that the rater judged to be unique in the context. The following dependent variables were obtained: total figurative phrases (FP), FP/1,000 words, novel figurative phrases (N), N/1,000, and N/FP%.

The two judges reached a high level of agreement on their scoring of FP (96%); an 88.9% agreement was obtained for classification of novel versus frozen. Only phrases that were mutually scored were used in the analysis. A statistical analysis was performed on each subject; LSD and dextroamphetamine sessions were individually compared to the placebo condition ($n = 7$ for each subject). Dunn's multiple comparison procedure was used to make the a priori comparison.

The results indicated that Patient 1 significantly increased ($p < .01$) his use of FP, FP/1,000 words, N, N/FP%, and N/1,000 words when under the influence of LSD. Patient 2 displayed LSD-induced increases in nonliteral language similar to the above-described findings for Patient 1, with the exception of FP and N/FP%

($p < .05$). In addition, FP/1,000 words was significantly increased ($p < .05$) for Patient 2 when under the influence of dextroamphetamine. Concerning Patient 3, the use of nonliteral language during psychoanalysis was not affected by either LSD or dextroamphetamine.

To sum up, the hypothesis that LSD increases the patient's use of novel figurative language in the course of psychoanalysis has been supported in two out of three case studies. However, it should be noted that the overall therapeutic value of psychotomimetics has not been demonstrated by this study. Although LSD does apparently increase the use of novel metaphors, and there is evidence that figurative language is associated with an important therapeutic process (insight), there is no evidence that drug-induced imagery will have the same beneficial effects as images that occur naturally.

Psychometric Correlates of the Mosher Forced Choice Guilt Inventory

Kevin E. O'Grady
University of Connecticut

Louis H. Janda
Old Dominion University

One-hundred one male and 135 female undergraduate psychology students were administered the Mosher Forced Choice Guilt Inventory (MFCGI), which consists of subscales measuring Sex Guilt, Hostility Guilt, and Morality-Conscience Guilt; the Repression-Sensitization Scale; the State-Trait Anxiety Inventory; the California F Scale; the Marlowe-Crowne Social Desirability Scale; and the Adult Nowicki-Strickland Locus of Control Scale. Inspection of correlations and principal component solutions for each sex indicated that guilt emerges as a construct separate from anxiety or authoritarianism. The applicability of the male form of the MFCGI for use with females is discussed.

The Mosher Forced Choice Guilt Inventory (MFCGI; Mosher, 1966) consists of 79 forced-choice items intended to measure three theoretically independent aspects of guilt: sex guilt (SG), hostility guilt (HG), and morality-conscience guilt (MCG). The purpose of the present research plan was twofold. First, an examination of the literature indicated the importance of assessing the relationship between the subscales of the MFCGI and several other personality inventories. Second, because the 1966 MFCGI, originally intended for use with males, has been used to measure guilt in females, an assessment of the factor structure in males and females of the 1966 MFCGI in relation to these other scales also seemed called for.

The MFCGI, together with the Repression-Sensitization (R-S) Scale; the California F Scale (F); the Adult Nowicki-Strickland Locus of Control (I-E) Scale; the State-Trait Anxiety Inventory (STAI), A-Trait form; and the Marlowe-Crowne Social Desirability Scale (M-C SDS) were completed by 236 undergraduate psychology students (101 males, 135 females). Separate principal components solutions for each sex were then obtained from the matrix of intercorrelations of the test scores. In each case three principal components with eigenvalues greater than 1.0 were retained and were rotated to

orthogonal simple structure using the normalized varimax method (see Table 1).

The results of the two principal components analyses were then compared using a technique developed by Schönemann and Carroll (1970). This procedure, a generalization of the orthogonal Procrustes problem, uses a least squares approach to fit one matrix to another. The overall degree of correspondence between the two matrices is provided by a measure of normalized symmetric error (ϵ). Fitting the male rotated component loadings to the female rotated component loadings indicated that the inventories were assessing the same underlying dispositions in the two groups ($\epsilon = .013$).

The first component, accounting for 31.2% of the total variance for the male sample, and 31.9% in the female sample, was labeled *admission of anxiety*. For males, the primary loadings ($\geq |\pm .5|$) consisted of the R-S (.892), F (.607), STAI (.852), and I-E (.674) scales. Primary loadings for females consisted of the R-S (.929), STAI (.892), I-E (.715), and M-C SDS ($-.548$) scales.

The second component, accounting for 26.9% of the total variance for the male sample and 25.7% in the female sample, was almost entirely marked by the three guilt subscales of the MFCGI and clearly represents a general guilt factor. Male loadings were .704 for SG, .850 for HG, and .846 for MCG. Female loadings were .790 for HG, and .857 for MCG, and .425 for SG.

The third component, accounting for 13.5% of the total variance for the male sample and 15.0% in the female sample, seemed to be largely determined by authoritarianism in both

2. F	.24		.37	.32	.07	.21	.16	-.09
3. STAI	.82	.11		.39	-.24	-.09	.20	.07
4. I-E	.56	.27	.51		-.15	.01	.03	.04
5. M-C SDS	-.41	.06	-.35	-.17		.27	.23	.09
6. SG	-.06	.39	-.01	.04	.25		.61	.38
7. MCG	.06	.16	.06	-.01	.31	.51		.52
8. HG	.11	-.09	.13	.03	.16	.19	.45	
Males								
M	39.60	11.04	34.69	9.38	15.39	10.53	11.86	17.54
SD	17.80	4.91	8.47	3.87	5.54	7.08	4.58	5.86
Females								
M	43.76	10.82	37.50	10.20	15.93	12.81	13.44	19.52
SD	17.57	5.21	8.24	4.95	5.49	6.61	3.94	4.52

Note. R-S = Repression-Sensitization Scale; F = Authoritarianism Scale; STAI = State-Trait Anxiety Inventory; A-Trait Form; I-E = Internal-External Locus of Control Scale; M-C SDS = Marlowe-Crowne Social Desirability Scale; SG = Sex Guilt subscale, MCG = Morality-Conscience Guilt subscale, HG = Hostility Guilt subscale of the Mosher Forced Choice Guilt Inventory. The correlation for males are above the diagonal, and the correlations for females are below it. For males, $r(99) \geq .19$, $p < .05$; $r(99) \geq .25$, $p < .01$. For females, $r(133) \geq .17$, $p < .05$; $r(133) \geq .23$, $p < .01$.

groups. Male loadings were composed of the F (.644) and M-C SDS (.707) scales, along with a smaller loading for SG (.453). Female loadings primarily involved the F (.857) and SG (.717) scales.

Examination of the separate factor solutions, and the residual matrix (the matrix of differences between the matrix of best fit and the initial target matrix) provided through the Procrustes procedure, revealed that the lack of correspondence in the solutions was mainly due to the fact that the SG subscale loaded primarily on the second factor for males, with a secondary loading on the third factor, whereas this pattern was reversed for the female subjects.

These results generally support the notion that guilt is a construct identifiably different from anxiety or authoritarianism. Besides a nominal amount of shared variance with SD for SG ($r = .25$ for males, $r = .27$ for females) and MCG ($r = .23$ for males, $r = .31$ for females, all $ps < .01$), only three other significant relationships emerged that involve the subscales of the MFCGI: SG with F for males ($r = .21$; $p < .05$) and females ($r = .39$, $p < .01$), and MCG with STAI for males ($r = .20$, $p < .05$). In contrast, the three subscales of the MFCGI share a moderate amount of variance among themselves (ranging from 4% to 38% across the two groups). Together with the results of the multi-trait-multimethod analysis of Mosher (1966),

which indicated that the SG, HG, and MCG subscales of the MFCGI measure discriminately different aspects of guilt, this study, which indicates that guilt is a discriminately different construct from anxiety or authoritarianism, offers strong support for the construct validity of the MFCGI.

Conclusions regarding the use of the male form of the MFCGI with females remain tenuous. Although the intercorrelations of the three subscales of the MFCGI exhibited the same overall pattern in males and females, the female correlations were somewhat lower than the corresponding male correlations. Further, the difference in factor structure for SG in the male and female factor solutions suggests that the SG subscale may be measuring different dispositions in the two groups. A comparison of the item factor structure of the MFCGI between males and females would help to clarify this issue.

Clinical Application of a Broad-Spectrum Behavioral Approach to Chronic Smokers

Harry A. Lando and John A. McCullough
Iowa State University

The present investigation assessed the clinical applicability of a broad-spectrum behavioral treatment (aversion, contractual management, booster sessions, group contact and support) previously reported by Lando. The feasibility of reorienting non-abstinent subjects to maintained reduction was also assessed. Twelve of 16 subjects who completed treatment were abstinent at a 6-month follow-up (75%), and 2 others were smoking substantially less than at baseline. Results suggest that the previous findings are replicable and that this program can be applied on a self-supporting clinical basis. Additional work is needed to validate the maintained reduction procedure.

Lando (1977) has called for the application of promising laboratory approaches to smoking cessation on a clinical basis. In that article he described a broad-spectrum treatment consisting of aversion, contractual management, booster sessions, faded group contact, and support, which led to a 76% abstinence rate at a 6-month follow-up. The major purpose of the present study was to assess the applicability of this treatment in a cost-effective clinical program. The present study was also intended to provide a replication of the Lando (1977) findings, as well as to allow a preliminary assessment of an additional treatment component in which nonabstinent smokers are reoriented toward maintained reduction.

Treatment was conducted by the second author, who is an advanced psychology graduate student at Iowa State University. He followed the treatment procedures for aversion and maintenance outlined in a treatment manual published by Lando (1976). Participants were required to deposit \$20, of which \$10 was refundable. The remaining \$10 was sufficient to cover all costs of the program.

Subjects included 17 smokers. (M age was 35.7 years, M years as a smoker was 17.3, and M baseline smoking was 28.7 cigarettes per day.)

This investigation was supported by Grant 1 R01 CA22102-01, awarded by the National Cancer Institute, Department of Health, Education, and Welfare.

Requests for reprints should be sent to Harry A. Lando, Department of Psychology, Old Botany Hall, Iowa State University, Ames, Iowa 50011.

Procedures for record keeping were as described in previous studies.

Aversion included six treatment sessions over a 1-week period. In the current study all 17 subjects were seen in a single group. Sessions averaged approximately 45 minutes, including a prescribed 25-minute period of continuous smoking. Subjects were also instructed to smoke as much as possible on their own between sessions, with a daily minimum of twice their usual consumption.

Subjects were instructed to abstain following aversion, and they attended seven maintenance sessions at the termination of this phase of the program. Formal support was faded over time, with the initial session occurring within 48 hours and the second session taking place 5 days later. Three additional maintenance sessions were then held at weekly intervals, followed by two final sessions that took place 2 weeks apart. These sessions consisted primarily of group discussion and the signing of contracts. Subjects contracted to forfeit money for every cigarette smoked, to reward themselves for increasingly longer periods of abstinence, and to undergo 48 hours of booster aversion (rapid smoking) in the event of relapse. (A more detailed description of treatment is available elsewhere; Lando, 1976, 1977.)

In a departure from previous work, subjects who failed to remain abstinent following two booster treatments were reoriented toward maintained reduction. There appear to be a certain number of smokers for whom abstinence is virtually impossible. In the current study maintained reduction was explored as a possible alternative for these smokers. The same essential

contractual techniques that had been directed toward abstinence were adapted to a program of maintained reduction. Nonabstinent subjects contracted to limit their smoking to a set daily allotment (between 10 and 20 cigarettes). Subjects were maintained at this level rather than gradually reduced to minimize the likelihood that each remaining cigarette would become more reinforcing. Efforts were also made to minimize the reinforcing value of smoking by prescribing a stimulus control procedure in which smoking was confined to specified locations and was divorced from other rewarding activities. Subjects now forfeited money for every cigarette smoked *over* the daily allotment and rewarded themselves over increasingly longer intervals for adhering to targeted consumption.

Sixteen subjects completed treatment, with 1 other dropping out at the termination of aversion. Of the subjects who completed the program, 100% remained abstinent at Week 1. Two subjects relapsed during the 1st month following aversion, and 2 others reported relapse in the 4th month. This yielded a 2-month abstinence rate of 88% (14 of 16 subjects), and 4- and 6-month abstinence rates of 75% (12 of 16 subjects). If the person who dropped out of the program is counted as a treatment failure, the 6-month abstinence rate is 71%.

The two subjects who relapsed during the first month failed to respond to booster treatment and were placed on maintained reduction (12 subjects maintained abstinence for the entire 6 months and did not undergo booster aversion). The 2 subjects who relapsed during the 4th month had reverted to their original levels of smoking by the 6-month follow-up. (No pressure was placed on subjects to participate in booster sessions or maintained reduction following the 2-month maintenance program.) Both subjects who were assigned to maintained reduction contracted to limit their smoking to 20 cigarettes a day. (Both had previously been two-pack-a-day smokers.) One of these subjects averaged 13 cigarettes per day at the 4-month follow-up and 17 at the 6-month follow-up (more than 5 months after the maintained reduction program had been initiated). The other subject averaged 21 and 25 cigarettes per day at the 4- and 6-month follow-ups, respectively. Unfortunately, the appropriate contingencies were not fully implemented, with contractual responsibility left to subjects and apparently only loosely adhered to.

Overall, the present findings are extremely encouraging, primarily because they suggest that the successful program reported by Lando (1977) is both replicable and generalizable to a clinical context. Treatment was offered on a service basis using a programmed treatment manual. This was not a controlled laboratory study, nor was it intended to be. Rather, it was an exploratory assessment of the applicability of a cost-effective laboratory-based program as a self-supporting clinical treatment. By this criterion, the program was clearly successful: The results are comparable to those obtained by Lando (1977) and are among the most encouraging findings reported in the literature to date.

Caution is still indicated in interpreting these findings, however. Both the current study and that of Lando (1977) were based on relatively small numbers of subjects. Both studies were conducted in the same community, with a similar population of smokers. There is considerable need for replication of this program by other investigators in different settings. The fact that all subjects were seen in a single treatment group also limits the generalizability of the current findings.

Considerable group cohesiveness was again evident in the present program and may be due at least in part to the specific treatment techniques used. Subjects were repeatedly informed of the importance of their own efforts in aiding themselves and in supporting each other. Participation in the program itself represented a significant commitment both in undergoing the aversion and maintenance sessions and in remitting the \$10 fee. The commitment to the program (and to each other) seemed to be reinforced by the extremely encouraging initial outcome in which 100% of the participants remained abstinent throughout Week 1.

Another purpose of the present study was to assess the effectiveness of a maintained reduction program for nonabstinent subjects. Although such a program appears very promising, particularly in providing nonabstinent subjects with an alternative, it cannot be meaningfully evaluated on the basis of the current evidence. Only two subjects underwent maintained reduction, and although the program appeared to be at least moderately successful in both cases, the contractual and stimulus control procedures were not fully implemented. The possibility that these subjects might eventually resume their former levels of smoking must also be considered. In future work maintained reduction programs should be more carefully implemented, and care

Relationships Between Client Self-Perceptions of Self-Consciousness Levels and Therapist Awareness of These Perceptions

Robert G. Turner and Mae Keyson
Pepperdine University

The present study investigated the congruity between clients' self-perceptions related to self-consciousness and their therapists' awareness of these self-perceptions. Neurotic ($n = 47$) and psychotic ($n = 51$) clients completed the Self-Consciousness Scale (SCS) under standard self-descriptive instructions. Therapists completed the SCS as they thought their client would respond. In both samples of clients, therapist's reports were significantly correlated with client self-reports on subscales of the SCS indicating self-reflective habits (Private Self-Consciousness) and discomfort in the presence of others (Social Anxiety) but not on a measure of awareness of oneself as a social object (Public Self-Consciousness).

The Self-Consciousness Scale (SCS; Fenigstein, Scheier, & Buss, 1975) is a measure of individual differences in habitual self-focused attention. Factor analysis of the items in the scale revealed two components of self-consciousness. The factor labeled *Private Self-Consciousness* concerns habitual attendance to one's thoughts, motives, and feelings and thus measures self-reflective or introspective tendencies. High compared to low private self-consciousness subjects generate self-reports that are both more detailed (Turner, in press) and more predictively valid (Turner, 1978). The second factor, Public Self-Consciousness, was defined by a general awareness of the self as a social object and reflects a concern for social appearance. A third factor, Social Anxiety, also emerged from the analyses of the scale and reflects a measure of discomfort in the presence of others. Social anxiety presumably occurs as a possible reaction to public self-consciousness. (See Turner, Scheier, Carver, & Ickes, 1978, for a review of research involving these subscales.)

Fenigstein et al. (1975) argued for the importance of individual differences in client self-consciousness levels in determining both the choice and goals of therapy. The goals of therapy might be directed toward the modification of a component of self-consciousness, for ex-

ample, decreased social anxiety or increased insight and self-reflection.

A component of many therapeutic approaches consists of the therapist understanding the phenomenological world of the client. Since self-consciousness would seem to have broad clinical and behavioral implications (cf. Turner et al., 1978), it would be useful to know the extent to which therapists are aware of clients' self-perceptions as related to self-consciousness levels. For example, if the goal of a therapeutic program is to increase client insight, are therapists aware of the extent to which their clients consider themselves to be self-reflective or insightful? Therefore, the purpose of the present investigation was to determine the congruity between clients' self-perceptions related to self-consciousness and their therapist's awareness of these self-perceptions.

The sample of clients consisted of 47 outpatients of a private psychiatric center who were clinically diagnosed as psychoneurotic disorder and 51 resident patients of a private, non-profit psychiatric hospital who were clinically diagnosed as psychotic disorder (schizophrenic reaction). Each client was paired with the therapist directly in charge of administering the therapeutic program of the client. Part of the theoretical orientation of each therapist emphasized understanding the client's phenomenological world. There were four therapists directing programs for the neurotic sample (each having 8-17 clients) and seven directing programs for the psychotic sample (each having 3-13 clients).

Each client completed the SCS under standard self-descriptive instructions. Independently, ther-

** $p < .01$.

*** $p < .001$.

apists were instructed to "answer the items as you think the client would respond."

Table 1 presents correlations between self-reports and therapists reports of the scores of clients on the SCS subscales. In both samples the correlations of primary interest lie along the major diagonal. Completing the SCS as they thought their clients would, therapists generated subscale scores significantly correlated with the self-reports of their clients for private self-consciousness and social anxiety in both samples of clients. Thus therapists were significantly aware of the extent to which clients would report themselves to be self-reflective and uncomfortable as the object of public attention.

In both samples of clients, therapists' reports and self-reports on the Public Self-Consciousness subscale were not significantly correlated. To the therapists of the neurotic sample, public self-consciousness was related to client social anxiety levels. In the psychotic sample, client perceptions tended to be related to therapists' perceptions of the clients as self-reflective or socially anxious. Thus the therapists' reports of clients' public self-consciousness were neither significantly nor distinctively related to clients' self-reports of public self-consciousness.

The level of the off-diagonal correlations of public self-consciousness with private self-consciousness and social anxiety are consistent with intercorrelations of these subscales in single-sample data (Turner et al., 1978). It would appear that public self-consciousness is neither as salient nor as relevant to insight-based therapeutic processes as are private self-consciousness and social anxiety. Self-reflection is a primary goal of such approaches, and levels of social anxiety are immediately salient in group therapy

procedures that often are a part of insight therapeutic programs. Concern for how one appears to others (public self-consciousness) would not be relevant unless it resulted in discomfort in the presence of others or social anxiety. Thus normal levels of public self-consciousness would not appear to be particularly relevant in many insight therapeutic programs.

If the therapist is to facilitate the growth of self-insight in the client, awareness of self-perceptions that are relevant to the direction of therapy is imperative. A possibly fruitful area for future research would be to investigate the relationships between client self-perceptions and therapists' awareness of these perceptions in other important areas of client self-concept. Indications of common accurate and inaccurate perceptions might assist therapists in identifying areas requiring diligent attention if accurate client self-perceptions are to be achieved.

Situational Management, Standard Setting, and Self-Reward in a Behavior Modification Weight Loss Program

Stanley L. Chapman

Department of Rehabilitation Medicine
Emory University

D. Balfour Jeffrey

University of Montana

In a comprehensive weight loss program, overweight women exposed to instruction in self-standard setting as well as to situational management techniques lost more weight than those instructed only in situational management techniques. Addition of instruction in self-reinforcement to standard setting and situational management failed to produce additional weight loss. Findings illustrate the facilitative effect of teaching individuals to set specific, objective, and realistic goals for eating behaviors and weight and the difficulties of incorporating self-reward procedures in a comprehensive program.

Short-term behavioral programs have yielded promising results, but there has been insufficient research on the variables involved (Abramson, 1977). Although several investigators have found greater weight losses in individuals taught to reward themselves for changing eating habits or weight than in controls instructed to self-monitor eating and weight (e.g., Bellack, 1976; Mahoney, 1974), the role of standard setting as a component of self-reinforcement has not been adequately studied.

In the present study, 57 women, who ranged from 17.0% to 84.8% above ideal body weight ($M = 45.4$) on insurance tables were recruited from the community through newspaper ads. They ranged in age from 17 to 65 years ($M = 37.8$), and most came from a middle or upper-middle socioeconomic level. They deposited \$40, which was returned contingent on attendance at group meetings, and were divided into triplets of approximately equal body weights and percentages of overweight. Members of each triplet were assigned randomly to the three treatment groups, each of which met for 90 minutes for 8 consecutive weeks and for a follow-up meeting 8 weeks after treatment. Group meetings consisted of a private weigh-in and presentation and discussion of specific behavioral techniques to be used during the following week. Three therapists, all of whom were familiar with behavior modification but who were in-

experienced in behavioral treatment for weight, rotated as leaders for the three groups. They were unaware of the hypotheses of the study and did not set standards or reward group members verbally for any eating behaviors or weight losses.

Treatment groups included a situational management group (SM), which focused mainly on the control of environmental stimuli that lead to overeating, as outlined by Ferguson (1975). Instructions in self-monitoring, stimulus control techniques, chaining, exercise, and diet were included. A second group, the self-standard setting group (SS), received the same instructions as Group SM, but they also were taught to write down standards each week for changes in weight and eating behaviors. SS participants were encouraged to set goals that they had an excellent chance to achieve and to make them specific, such as "I will eat a moderate breakfast (below 500 calories) each morning," rather than "I will never eat candy again." (See Jeffrey & Katz, 1977, for more information on realistic standard setting and other behavioral techniques.) Therapists stressed the importance of standards and examined each participant's standards weekly.

The self-reward (SR) group received the same training as Groups SM and SS, but members also were instructed weekly to make contracts with themselves and others to receive verbal and material rewards contingent on successful weight losses and small daily achievements in changing eating behaviors. Suggested examples included telling oneself one performed well, arranging small treats such as a leisurely bath or a trip to the beauty parlor, and arranging a special outing with one's spouse.

In addition, members of this group deposited an extra \$17.50, which was used as monetary

Thanks are extended to Patricia Chapman, Alan Torppa, and Patricia Weis, who served as therapists for this study.

Requests for reprints and for an extended report of this study should be sent to D. Balfour Jeffrey, Department of Psychology, University of Montana, Missoula, Montana 59812.

rewards for improvement in the form of a check for \$1.25 for eating habit changes and a check for \$1.25 for weight loss each week for 7 weeks of treatment. Participants were instructed to reward themselves weekly by taking their respective checks only if they reached their respective weekly goals for eating and weight loss. If they did not reach their goals, they were instructed *not* to reward themselves, but rather to deposit the checks through a slot in a locked box outside the meeting room.

One member of each group dropped out of treatment, and one SR group member was excluded from follow-up analyses after developing thyroid difficulties. Mean weight changes were compiled for each group for a 7-week baseline period, for 7 weeks of treatment, and for 1 follow-up 8 weeks after treatment. These results were as follows: Group SM ($n=19$) gained 1.84 pounds (.83 kg) during baseline, lost 4.03 pounds (1.82 kg) during treatment, and lost an additional 1.13 pounds (.51 kg) after treatment; Group SS ($n=18$) gained .16 pounds (.07 kg) during baseline, lost 7.47 pounds (3.39 kg) during treatment, and lost 1.97 pounds (.89 kg) after treatment; Group SR ($n=17$) gained 1.57 pounds (.71 kg) during baseline, lost 4.71 pounds (2.14 kg) during treatment, and lost 1.46 pounds (.66 kg) after treatment. One-way analyses of variance with repeated measures indicated that all three groups lost significant amounts of weight during the treatment and from pretreatment to follow-up (all p 's $< .01$). Welch's t test revealed that Group SS lost significantly more weight than Group SM during treatment and from the beginning of treatment to the end of follow-up ($p < .05$), but all other group comparisons were nonsignificant.

At posttreatment and at follow-up, members of each group rated the helpfulness of 19 behavior change techniques. "Setting standards for behavior" received the highest mean rating in the SS group and also was rated highly in Group SR, whereas Group SR rated "rewarding self" and "getting others to reward me" as the two least helpful techniques that they learned. All correlations calculated between weight change during and after treatment and self-reports of standard setting for eating habits reached the .05 level of significance for the SS and SR groups combined. These coefficients, which ranged from $-.343$ to $-.609$, were calculated from self-reports on the closeness of attention paid to eating standards, the number of behaviors for which standards were set, the frequency of setting standards for eating, and the success in reaching them. Closeness of attention paid to weight standards correlated significantly

with weight loss after treatment but not during treatment. Questionnaire data also showed that SR participants gave themselves a mean of only two verbal rewards per week at home and one material reward every 3-4 weeks.

The significant weight loss of the SM group adds further evidence that weight loss can be produced without programming external or self-reinforcement. The data also support the superiority of teaching individuals to set standards for eating and for losing weight in addition to teaching situational management over instruction in situational management alone. On the other hand, comprehensive instruction in self-reward in addition to standard setting and situational management did not facilitate further weight loss as predicted. This instruction may have been incompatible with instruction in the standard setting or it may have caused participants to be overloaded with information. However, these possibilities were not consistent with questionnaire and anecdotal data, which indicated that the self-reward techniques were seen as being of little benefit, were used seldom, and made participants feel anxious and overly pressured to achieve standards. Many of them reported that losing weight was so important to them anyway that instruction in self-reward was unnecessary.

It is possible that implicit training in setting standards rather than training in self-reinforcement was the more important factor in previous studies in which members of self-reward groups have shown greater weight losses than controls. External or self-standard setting was embedded in the self-reward condition but not in the control conditions of these studies. The findings of this study do not imply that self-reinforcement is unimportant, but they illustrate the difficulties of incorporating self-reward procedures in a comprehensive clinical program.

Psychotherapeutic Styles: Self-Perceptions of Therapists Varying on A-B Type and Experience

William B. Goodwin
Yale University

The possibility that psychotherapeutic styles might differ as a function of A-B type or experience was investigated by interviewing 40 A and B experienced and inexperienced psychotherapists on a wide range of issues relating to therapeutic approach and style. The importance of the experience level of the therapist was confirmed by therapists' self-descriptions: Experienced therapists seemed to conform less to conventional stereotypes of the traditional psychotherapist than did inexperienced therapists, and experienced therapists appeared to emphasize immediacy and encounter while deemphasizing detachment, diagnoses, and psychodynamic interpretations. At the same time, self-perceived differences between A and B therapists were not apparent.

One approach to the study of psychotherapy that has seldom been tried is to interview the therapists themselves. Schiffman, Carson, and Falkenberg (Note 1) A-B scale scores were obtained by mail from a large sample of trainee therapists at the Yale University Department of Psychiatry. A-B scores were also available for a number of experienced therapists who had participated in a previous study (Goodwin, 1975). Only male clinicians with at least 1 year of therapeutic experience and who were clearly Type A or Type B as defined by the approximate outer quartiles of the distribution (14 or above = A; 8 or below = B) were invited to participate. Forty of the 41 therapists who were contacted consented to be interviewed about their own approach to psychotherapy, in exchange for a précis of the results upon completion of the study. Each clinician was then scheduled for a 1-hour standardized tape-recorded interview in his own office, followed by a brief questionnaire to elicit extent of use of particular techniques.

All scales and coding systems for interview responses were constructed after preliminary inspection of the range of responses. The interviewer (myself) and corater blindly rated the

material. I was blind to therapists' A-B type until the coding was completed.

Results

Interscorer reliabilities for all response scales and category systems were quite high, with many in the .90s. Mean A-B scores were 16.75 for As ($n = 20$, $SD = 1.92$) and 6.05 for Bs ($n = 20$, $SD = 1.40$). Therapists still in training averaged 2.10 years of experience; experienced therapists averaged 9.95 years of experience.

Outcome Index

For responses to four questions regarding retrospective assessment of psychotherapy outcome, an outcome index was devised based on a simplified version of the A-B interaction hypothesis: Positive outcome with schizoids or negative outcome with neurotics was scored 3; positive outcome with neurotics or negative outcome with schizoids was assigned 1; and other responses were assigned 2. The questions addressed the individual patient with whom the therapist had enjoyed the greatest success, the one with whom he had encountered the least success, and the type of patient with whom he had experienced the greatest and least success. Scores for these questions were summed, and the resulting linear combination was subjected to a 2×2 analysis of variance. No main effect for A-B type was found nor were other effects significant.

Factor Analysis

The bulk of the responses were subjected to a principal components factor analysis; varimax rotations were then computed for a four-factor

This article is based on a doctoral dissertation submitted to the Department of Psychology at Yale University under the supervision of Donald M. Quinlan and Jesse D. Geller.

Requests for reprints, an extended report including the factor loadings matrix, and copies of the interview schedule should be sent to William B. Goodwin, 599 Whitney Avenue, Apartment 1A, New Haven, Connecticut 06511.

solution. Factor labels, and proportions of variance accounted for, were 1: Human Potential Movement (18.4%); 2: Rogerian Style (14.1%); 3: Modified Psychoanalytic Style (13.1%); and 4: Agitated Involvement Versus Calm Neutrality (11.4%). A 2×2 multivariate analysis of variance was computed on the four factor scores for each therapist, treating A-B type and experience level as the predictors. Neither the overall A-B Type \times Experience Level interaction nor the A-B main effect were significant. Thus, a pervasive difference in style between A and B psychotherapists was not evident.

Experience Level

The multivariate main effect for experience level was significant ($p < .017$), however, and chiefly reflected experienced therapists' low scores on the Modified Psychoanalytic Style factor (weighted $-.905$ in the discriminant function) and high scores on the Human Potential Movement factor (weighted $.514$ in the discriminant function). Based on the most salient components of these two factors—and noting univariate F s where significant—inexperienced therapists seemed to perceive themselves as rarely using an advice-giving educational approach, $F(1, 16) = 4.73$, $p < .036$; as not personally involved with, $F(1, 16) = 6.15$, $p < .018$, or self-disclosing toward their patients; as making extensive use of psychodynamic interpretations, $F(1, 16) = 6.31$, $p < .017$; as seeing diagnoses as very useful, $F(1, 16) = 7.03$, $p < .012$; as not expressing negative reactions readily to patients, $F(1, 16) = 4.82$, $p < .035$; and as being inclined to reject the "sociopathology of mental illness" viewpoint of Thomas Szasz.

Experienced therapists perceived themselves as not using depth interpretations frequently; as tending to use an advice-giving educational approach; as being more personally involved with and self-disclosing toward their patients; as expressing negative reactions readily; as using bantering to a moderate extent; as finding diagnoses comparatively useless; and as tending to agree with the viewpoint of Thomas Szasz.

Possible Covariates

No significant differences between As and Bs were found with respect to type of practice, place of training, avowed theoretical orientation, or profession, but inexperienced therapists more frequently had institutional practices (100% vs. 60%) and were more frequently trained at Yale University than their experienced colleagues (100% vs. 30%). In addition, a higher

proportion of the inexperienced (85%) than of the experienced therapists (40%) were psychiatrists. The possibility that experience-level differences were actually mediated by profession differences was indirectly evaluated by means of a profession by experience level 2×2 multivariate analysis of variance of the factor scores: No main or interaction effects for profession were found, however.

Discussion

Perhaps broad differences in clinical style between A and B therapists do not exist, although it remains possible that such differences may not be reflected in therapist self-description or may not be aligned along dimensions studied here.

Perhaps the most striking thing about the self-descriptive portraits for the two experience levels is that popular stereotypes coincide more closely with the self-characterizations of the inexperienced therapists. It could be that one of the major effects of accruing therapeutic experience is a moving away from traditional role expectations toward higher degrees of personal involvement and encounter with patients. Longitudinal studies of professional psychotherapists are obviously needed to resolve this question.

Finally, if such differences between experienced and trainee therapists can be replicated in other populations using other methods, what is it about therapist experience level that creates these differences? Maturation, aging, increased life experiences, change in socioeconomic status, and possible additional training are a few alternatives to the obvious increase in psychotherapy experience. By partitioning experience level into more subgroupings, future research might also attempt to ascertain whether any such differences emerge gradually and continuously or abruptly and discontinuously.

CHARLES C THOMAS • PUBLISHER

SEX-RELATED COGNITIVE DIFFERENCES: An Essay on Theory and Evidence by Julia A. Sherman. Biological theories, including purported sex differences in brain lateralization, and related sociocultural determinants are discussed. *cloth-\$16.25, paper-\$12.25*

COUNSELING IN COMMUNICATIVE DISORDERS edited by R. E. Hartbauer. Each chapter focuses on a particular communicative problem, giving a general overview of the disorder, counseling techniques and procedures, and suggestions for evaluation of effectiveness. *\$18.25*

MUSIC THERAPY: An Introduction to Therapy and Special Education Through Music (2nd Ptg.) by Donald E. Michel. A history of music therapy, its basic theoretical rationales, and its applications in therapy, rehabilitation, and special education are presented. *\$11.25*

THE USE OF ALTERNATIVE MODES FOR COMMUNICATION IN PSYCHOTHERAPY: The Computer, The Book, The Telephone, The Television, The Tape Recorder by David Lester. The author discusses each communication mode and its unique psychotherapeutic qualities. *\$12.25*

GROUP COUNSELING AND GROUP PSYCHOTHERAPY WITH REHABILITATION CLIENTS edited by Milton Seligman. Practical applications of group strategies are given particular emphasis along with group methods with vocational or occupational goals. *cloth-\$19.00, paper-\$14.75*

CRISIS INTERVENTION AND HOW IT WORKS by Romaine V. Edwards. The primary focus is on the author's proven method of crisis counseling. *\$9.25*

THEORIES AND METHODS OF GROUP COUNSELING IN THE SCHOOLS (2nd Ed.) edited by George M. Gazda. Topics include group methods for use with the early school child, family group counseling, and Adlerian group consultation. *\$18.25*

A PRIMER ON SCHOOL MENTAL HEALTH CONSULTATION by Morton I. Berkowitz. The basics of the consultation process — how to start school consultation, what goes on once it is in progress, and to what ends it may conclude — are presented. *\$11.50*

MENTAL EXAMINER'S SOURCE BOOK edited by Julian C. Davis and John P. Foreyt. Chapters include the classification of mental retardation, objective and projective personality testing, intelligence testing and the mental status examination. *\$16.75*

THE HAND TEST: A New Projective Test with Special Reference to the Prediction of Overt Aggressive Behavior (5th Ptg.) by Barry Bricklin, Zygmunt A. Piotrowski and Edwin E. Wagner. The text covers daily use of the test in clinical practice, including diagnostic procedures for individual cases. *\$8.25*

THE CARE AND MANAGEMENT OF THE SICK AND INCOMPETENT PHYSICIAN by Robert C. Green, Jr., George J. Carroll and William D. Buxton. The authors detail the management, prevention and identification of problems which impair the ability of a physician to perform adequately. *\$10.00*

BASIC APPROACHES TO GROUP PSYCHOTHERAPY AND GROUP COUNSELING (2nd Ed., 2nd Ptg.) edited by George M. Gazda. Experts in the field summarize such techniques as psychodrama, reality therapy, rational-emotive therapy and gestalt therapy. *\$19.50*

PSYCHIATRIC PROBLEMS IN OPHTHALMOLOGY edited by Jerome T. Pearlman, George L. Adams and Sherwin H. Sloan. Discussions of the eye and the "I," reactions to the loss of sight, and eye symptoms with no organic disease are included along with helpful diagnostic and management procedures. *\$14.50*

HUMAN BEHAVIOR GENETICS compiled and edited by Arnold R. Kaplan. In addition to such topics as basic human genetics, measuring human behavior, and genetic factors in intelligence and personality development, the book shows the need for careful controls and conservative judgement. *\$28.00*

CASE STUDIES OF THE CLINICAL INTERPRETATION OF THE BENDER GESTALT TEST: Illustrations of the Interpretive Process for Graduate Training and Continuing Professional Education by Clifford M. DeCato and Robert J. Wicks. This book establishes the Bender Gestalt Test (BGT) as an effective means for assessing personality dynamics, developmental level and psychopathology. *\$11.25*

TECHNIQUES FOR BEHAVIOR CHANGE: Applications of Adlerian Theory (3rd Ptg.) compiled and edited by Arthur G. Nikelly. Sections include assessment, group and individual therapy, and techniques for dealing with special problems. *\$12.25*

THE EMOTIONALLY DISTURBED CHILD: A Book of Readings (2nd Ptg.) compiled and edited by Larry A. Faas. The text covers man's approach to defining emotional disturbances and offers discussion on the identification and dynamics of emotionally disturbed children. *\$16.75*

Clinical Evaluation of Young Children with the McCarthy Scales

By ALAN S. KAUFMAN Ph.D.
and NADEEN L. KAUFMAN, M.A., Ed.D.

Clinical Evaluation of Young Children with the McCarthy Scales is probably the only book available on the clinical interpretation of the McCarthy test. The authors, who have drawn on years of research and clinical experience with the test, share a psychometric-clinical-learning disabilities orientation towards assessment. In addition, both authors were involved in the development of the scale prior to its publication and have published extensively on the battery during the past five years. Crucial topics such as screening for learning problems, administration tips, and writing, case reports are also featured. Readers and users of this unique work will gain invaluable insight into the McCarthy profile of any children tested.

1977, 320 pp., \$16.50 ISBN: 0-8089-1013-2

The Personal Sphere Model

By RAOUL A. SCHMIEDECK, M.D.

The Personal Sphere Model offers reliable and valid data as an instrument for the assessment of object relationships and for personality research in general. It is a projective test in which interpersonal relationships are presented by drawings. Both a manual for the Personal Sphere Model and an account of its development, this book contains instructions, norms, studies in reliability and validity, examples, and reviews of supporting work.

1978, 240 pp., \$18.50 ISBN: 0-8089-1093-0

Contributions to the Psychopathology of Schizophrenia

Edited by BRENDAN A. MAHER

This collection contains reprints of important articles—both empirical reviews and theoretical formulations—on schizophrenia that have appeared in *Progress in Experimental Personality Research*. It provides a comprehensive review of the advances in research on schizophrenia over the past 12 years. All articles except the last are accompanied by postscripts written by the article authors, indicating changes that have occurred in their thinking and new data that bear on their original formulations. Clinical psychologists, psychiatrists, psychoanalysts, and psychopathologists; and abnormal, personality, developmental, cognitive, and experimental psychologists will all find interesting perspectives on their work and the history of its development in these seminal articles.

CONTENTS: P. H. Venables, Input Disfunction in Schizophrenia. Postscript. L. J. Chapman et al., A Theory of Verbal Behavior in Schizophrenia. Postscript. I. I. Gottesman, Contributions of Twin Studies to Perspectives in Schizophrenia. Twin Studies and Schizophrenia a Decade Later. W. E. Broen, Jr., and L. H. Storms, A Theory of Response Interference in Schizophrenia. Response Disorganization and Narrowed Observation. J. M. Neale and R. L. Cromwell, Attention and Schizophrenia. Postscript. P. Magaro, Theories of the Schizophrenic Performance Deficit.

1977, 400 pp., \$11.25 ISBN: 0-12-465250-6

Progress in Experimental Personality Research

VOLUME 6

Edited by BRENDAN A. MAHER

FROM THE PREVIEWS:

"... unusually excellent scholarly and closely reasoned review... highly recommended."

—AMERICAN JOURNAL OF PSYCHIATRY

"... bound to be arresting to many readers, and further demonstrates that experimental psychology is 'not so much a subject as a way of life' in the reduction of scientific uncertainty."

—Vernon Hamilton in NATURE

This serial publication is designed to synthesize current significant developments in the study of personality for psychologists, psychopathologists, psychiatrists, sociologists, educators, and other students of behavioral science. Contributions range from original works in important technical areas to summaries of data and integrated reviews of present knowledge.

1978, 368 pp., \$23.00 ISBN: 0-12-541408-0

AHSEN'S EPT

Description: Ahsen's Eidetic Parents Test (EPT) elicits eidetic images of parents, in the mind of the subject, in 30 situations. Each response is a triadic experiential unit — an image(I), a somatic response(S), and a meaning(M). A precise test for localizing personality structures, somatic and emotional patterns and psychological themes in the form of images which do not change unless transformed through therapeutic dynamics.

"A methodological advance"

— *American Journal of Psychiatry*

"An important addition to the fear inventories and reinforcement schedules currently in use...a rapid and effective method."

— *Behavior Therapy*

"An exciting and ingenious way of getting at conflict areas and providing a rich source of material for therapeutic sessions. A new and intriguing device for personality assessment"

— *Contemporary Psychology*

Uses: Easily administered within one hour (brief) or longer (comprehensive), if desired. A structured interview which elicits valid developmental and personality data, also an initial diagnostic instrument or therapy process, for use with adults and children. Full instructions for psychological report writing.

"Therapeutic as well as diagnostic and fact finding" — *The International Journal of Clinical and Experimental Hypnosis*

Learned Helplessness as a Model of Depression

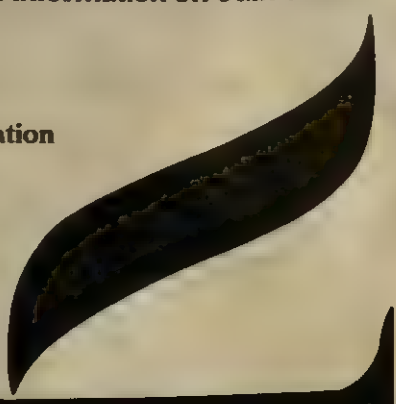

**Special issue of the
Journal of Abnormal Psychology,
February 1978.**

The issue serves as a forum to investigate the validity and adequacy of the learned helplessness model of depression in humans and includes both critical and supportive theoretical and empirical articles with comments.

L. Rowell Huesmann is guest editor. Richard A. Depue, Martin E. P. Seligman, Charles G. Costello, Robert C. Smolen, and Alexander M. Buchwald are among the contributors.

Copies of the special issue are available at \$6 each, prepaid. Discounts on bulk orders are also available. To order single copies or for more information on bulk orders write:

Have the life of your time!

A lot of your colleagues do!

For the past 13 years, many members of the APA have taken advantage of their eligibility to purchase life insurance at special group-rate savings. And each year they've found that they get more out of life — because the low cost term rates they pay have been further reduced by not less than 20% in premium credits. A reduction that is unheard of in today's inflationary economy. You can join your colleagues by applying for life

insurance coverage in amounts ranging from \$10,000 to \$100,000. If you already have life insurance, this is an inexpensive way to add to the coverage you now have. And you get the additional benefit of accidental death and dismemberment coverage. Also, there's an optional life coverage available for your spouse and children.

**So don't wait. Fill out the coupon below and send it in now, because —
Now is the time to have the life of your time.**

Mr. Harold Belcher, Administrator
APA Insurance Plans
Liberty Life Assurance Company of Boston
175 Berkeley Street
Boston, Massachusetts 02117

Please send me more information about APA group-rate life insurance.

Need an individual test which *quickly* provides a stable and reliable estimate of intelligence in 4 or 5 minutes per form? Has three forms? Does not depend on verbal production or subjective scoring? Can be used with the severely physically handicapped (even paralyzed), if they can signal yes-no? Handles two-year-olds and superior adults within the same short series of items and the same format? Has been painstakingly standardized? Builds rapport with intrinsically interesting and simple procedures based on multiple drawings?
